Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Table of Contents

Contributors	ix
Preface.....	xvii
Acknowledgements	xix

SECTION 1: ORGANISATION, DELIVERY AND OUTCOME OF NEONATAL CARE..... 1

Chapter 1	
Epidemiology	3
<i>Alison Macfarlane, Miranda Mugford</i>	
Chapter 2	
Organisation and Evaluation of Perinatal Care.....	53
<i>Neil Marlow</i>	
Chapter 3	
Outcome following Preterm Birth.....	71
<i>Neil Marlow, Samantha Johnson</i>	
Chapter 4	
Developmental Care	89
<i>Angela Huertas-Ceballos, Gillian Kennedy</i>	
Chapter 5	
Counselling and Support for Parents and Families	95
<i>Ian A Laing, Chinthika Piyasena, Hazel E McHaffie</i>	
Chapter 6	
Ethical and Legal Aspects of Neonatology.....	102
Chapter 6.1	
Ethics.....	103
<i>John Wyatt</i>	
Chapter 6.2	
The Law.....	106
<i>Bertie Leigh, Janet M Rennie</i>	
Chapter 7	
Science and the Emergence of Neonatal Medicine	115
<i>Malcolm Chiswick</i>	

SECTION 2: PRENATAL LIFE..... 127

Chapter 8	
Basic Genetics.....	129
<i>Andrew Green</i>	
Chapter 9	
Antenatal Diagnosis and Fetal Medicine	141
<i>Dharmintra Pasupathy, Mark Denbow, Phillipa Kyle</i>	
Chapter 10	
Fetal Growth, Intrauterine Growth Restriction and Small-for-Gestational-Age Babies	175
<i>Imelda Balchin, Donald Peebles</i>	
Chapter 11	
Maternal Illness in Pregnancy.....	189
<i>David Williams, Lila Mayahi</i>	
Chapter 12	
Obstetrics for the Neonatologist	207
<i>Sukrutha Veerareddy, Maggie Blott</i>	

SECTION 3: CARE AROUND BIRTH..... 221

Chapter 13	
Resuscitation and Transport of the Newborn.....	223
Chapter 13.1	
Stabilisation and Resuscitation of the Newborn	223
<i>Colm O'Donnell, Colin J Morley</i>	
Chapter 13.2	
Neonatal Transport	239
<i>Steve Kempley, Nandiran Ratnavel</i>	

SECTION 4: GENERAL NEONATAL CARE..... 245

Chapter 14	
Examination of the Newborn	247
<i>Janet M Rennie</i>	

Chapter 15		SECTION 5: DISORDERS OF THE NEWBORN.....	443
Temperature Control and Disorders.....	263	Chapter 27	
<i>Anoo Jain</i>		Pulmonary Disease of the Newborn	445
Chapter 16		Chapter 27.1	
Infant Feeding	277	Physiology.....	448
Chapter 16.1		<i>Anne Greenough, Anthony D Milner</i>	
New Perspectives in Neonatal Nutrition.....	278	Chapter 27.2	
<i>Mary Fewtrell, Sirinuch Chomtho</i>		Acute Respiratory Disease.....	468
Chapter 16.2		<i>Anne Greenough, Anthony D Milner</i>	
Feeding the Full-Term Baby.....	297	Chapter 27.3	
<i>Mary Fewtrell, Alan Lucas</i>		Chronic Lung Disease.....	552
Chapter 16.3		<i>Anne Greenough, Anthony D Milner</i>	
Feeding Low-Birthweight Infants	309	Chapter 27.4	
<i>Mary Fewtrell, Sirinuch Chomtho, Alan Lucas</i>		Apnoea and Bradycardia.....	571
Chapter 17		<i>Simon Hannam</i>	
Parenteral Nutrition.....	321	Chapter 27.5	
<i>Pamela Cairns</i>		Malformations of the Lower Respiratory Tract	581
Chapter 18		<i>Grenville F Fox</i>	
Fluid and Electrolyte Balance.....	331	Chapter 27.6	
<i>Neena Modi</i>		Diaphragmatic Hernia	593
Chapter 19		<i>Carmen Turowski, Mark Davenport</i>	
Intensive Care Monitoring and Data Handling	345	Chapter 27.7	
<i>Andrew Lyon</i>		Airway Problems	604
Chapter 20		<i>Gavin Morrison</i>	
Care of the Normal Term Newborn Baby.....	361	Chapter 28	
<i>Patrick H T Cartledge, Divyen K Shah,</i>		Cardiovascular Disease	617
<i>Janet M Rennie</i>		<i>Robert W M Yates</i>	
Chapter 21		Chapter 29	
Care of the Normal Small Baby and Convalescent		Gastroenterology.....	671
NICU Graduate	375	Chapter 29.1	
<i>Kate Farrer</i>		Neonatal Jaundice.....	672
Chapter 22		<i>N Kevin Ives</i>	
Neonatal Complications following Diabetes in		Chapter 29.2	
Pregnancy	387	Liver Disease.....	693
<i>Jane M Hawdon</i>		<i>Giorgina Mieli-Vergani, Nedim Hadžić</i>	
Chapter 23		Chapter 29.3	
Twins.....	395	Gastrointestinal Disorders.....	706
<i>Edile Murdoch, Gordon Smith</i>		<i>Simon Newell</i>	
Chapter 24		Chapter 29.4	
Pharmacology.....	405	Congenital Defects and Surgical Problems.....	724
<i>Imti Choonara, John McIntyre, Sharon Conroy</i>		<i>Ian Sugarman, Mark D Stringer, Alistair G Smyth</i>	
Chapter 25		Chapter 30	
Neonatal Analgesia	419	Haematology	755
<i>Steven M Sale, Anoo Jain, Judith Meek</i>		<i>Irene A G Roberts, Neil A Murray</i>	
Chapter 26		Chapter 31	
The Baby of a Substance-Abusing Mother	431	Malformation Syndromes	791
<i>Cassie Lawn, Neil Aiton</i>		<i>Oana Caluseriu, William Reardon</i>	

Chapter 32 Neonatal Dermatology.....	819 <i>Maureen Rogers</i>	Chapter 40 Neurological Problems in the Newborn.....	1065
Chapter 33 Ophthalmology.....	837 <i>Brian Fleck</i>	Chapter 40.1 Examination of the Nervous System	1067 <i>Janet M Rennie, Angela Huertas-Ceballos</i>
Chapter 34 Metabolic and Endocrine Disorders.....	849	Chapter 40.2 Neonatal Seizures.....	1080 <i>Geraldine Boylan, Janet M Rennie</i>
Chapter 34.1 Disorders of Metabolic Homeostasis in the Neonate	850 <i>Jane Hawdon</i>	Chapter 40.3 Intracranial Haemorrhage and Perinatal Stroke (Arterial and Venous) at Term	1099 <i>Divyen K Shah, Janet M Rennie</i>
Chapter 34.2 Endocrine Disorders	868 <i>Tim Cheetham, Daniel J Schenk</i>	Chapter 40.4 Hypoxic-Ischaemic Brain Injury.....	1114 <i>Nicola J Robertson, Floris Groenendaal</i>
Chapter 34.3 Inborn Errors of Metabolism in the Neonate.....	906 <i>Simon A Jones, James E Wraith</i>	Chapter 40.5 Preterm Brain Injury	1156 <i>Leigh E Dyet, Janet M Rennie</i>
Chapter 34.4 Metabolic Bone Disease	920 <i>Nick Bishop</i>	Chapter 40.6 Hereditary and Degenerative Central Nervous System Disease	1182 <i>Peter G Barth</i>
Chapter 35 Disorders of the Kidney and Urinary Tract.....	927	Chapter 40.7 Muscle Disease in the Newborn	1189 <i>Adnan Y Manzur, Stephanie A Robb, Francesco Muntoni</i>
Chapter 35.1 Renal Function and Renal Disease in the Newborn	927 <i>Neena Modi</i>	Chapter 40.8 Central Nervous System Malformations	1200 <i>Cornelia Hagmann, Janet M Rennie</i>
Chapter 35.2 Urology	939 <i>Naima Smeulders, Duncan T Wilcox</i>	SECTION 6: PATHOLOGY, RADIOLOGY AND BIOCHEMISTRY	1225
Chapter 36 Neonatal Malignancy.....	953 <i>Roger D Palmer, Denise M Williams</i>	Chapter 41 The Perinatal Postmortem Examination	1227 <i>Martin A Weber, Sudhin Thayyil, Neil J Sebire</i>
Chapter 37 Orthopaedic Problems in the Neonate.....	967 <i>Christopher J Dare, N M P Clarke</i>	Chapter 42 The Clinical Biochemistry Laboratory.....	1239 <i>Ruth M Ayling</i>
Chapter 38 Neonatal Gynaecology	989 <i>D Keith Edmonds</i>	Chapter 43 Neonatal Imaging.....	1243 <i>Paul Humphries</i>
Chapter 39 Neonatal Infection.....	993	SECTION 7: PRACTICAL PROCEDURES	1259
Chapter 39.1 Immunodeficiency	994 <i>Andrew J Cant, Andrew R Gennery</i>	Chapter 44 Procedures and Iatrogenic Disorders.....	1261 <i>Sian Harding</i>
Chapter 39.2 Infection in the Newborn.....	1013 <i>Alison Bedford Russell, David Isaacs</i>

Contributors

NEIL AITON MBBS MD MRCPI FRCPCH

Consultant Neonatologist
Trevor Mann Baby Unit
Brighton & Sussex University Hospitals NHS Trust
Royal Sussex County Hospital
Brighton, UK

NICK ARCHER MA FRCP FRCPCH DCH

Consultant Paediatric Cardiologist, Honorary Clinical
Senior Lecturer
Department of Paediatric Cardiology
John Radcliffe Hospital
Oxford, UK

RUTH M AYLING PHD MRCPCH FRCP FRCPATH

Consultant Chemical Pathologist
Clinical Biochemistry
Derriford Hospital
Plymouth, UK

IMELDA BALCHIN BSC MBCHB MSC MRCOG MFSRH MD

Academic Clinical Lecturer and Specialist Registrar
Department of Epidemiology & Public Health
Health Care Evaluation Group
Institute for Women's Health
University College London Hospital NHS Trust
London, UK

PETER G BARTH MD PHD

Emeritus Professor in Paediatric Neurology
University of Amsterdam
Emma's Children Hospital
Amsterdam, Netherlands

ALISON BEDFORD RUSSELL BSC FRCPCH MD

Clinical Lead South West Midlands Newborn Network
(SWMNN)
Hon Associate Clinical Professor
Warwick Medical School
Neonatal Consultant Birmingham Women's Foundation Trust
Neonatal Unit
Birmingham, UK

NICK BISHOP MB CHB MRCP MD FRCPCH

Professor of Paediatric Bone Disease
Director, Children's Clinical Research Facility
Head, Academic Unit of Child Health
University of Sheffield, Sheffield Children's Hospital
Sheffield, UK

MAGGIE BLOTT FRCOG

Consultant Obstetrician and Labour Ward Lead
Elizabeth Garratt Anderson Wing
Obstetric Service
University College London Hospital NHS Trust
London, UK

ANN BOWRON BSC MSC FRCPATH

Clinical Biochemistry
Bristol Royal Infirmary
Bristol, UK

GERALDINE BOYLAN MA MSC PHD

Professor of Neonatal Physiology
Department of Paediatrics & Child Health
University College Cork and Cork University Maternity
Hospital
Cork, Ireland

PAMELA CAIRNS MB BCH MRCP MRCPCH DCH MD

Consultant Neonatologist
Department of Child Health
St Michael's Hospital
Bristol, UK

OANA CALUSERIU MD

Medical Genetics Resident, University of Calgary
Alberta Children's Hospital
Department of Medical Genetics
Calgary, Canada

ANDREW J CANT BSC MD FRCP FRCPC

Professor of Paediatric Immunology
Paediatric Immunology and Infectious Diseases Unit
Great North Children's Hospital
Newcastle-Upon-Tyne, UK

PATRICK H T CARTLIDGE MB CHB DM FRCPC FRCP

Department of Child Health
Cardiff University
Cardiff, UK

TIM CHEETHAM BSC MBCHB MD MRCP MRCPCH

Institute of Human Genetics, Newcastle University
Children's Out Patient Department
Royal Victoria Infirmary
Newcastle-upon-Tyne, UK

MALCOLM CHISWICK MD FRCP(Lond) FRCPC FRCOG DCH

Honorary Professor of Neonatal Medicine
University of Manchester, UK
Honorary Consultant in Neonatal Medicine
St Mary's Hospital
Manchester, UK

SIRINUCH CHOMTHO MD PHD

Lecturer, Nutrition Unit
Department of Pediatrics
Faculty of Medicine
Chulalongkorn University
Bangkok, Thailand

IMTI CHOONARA MB CHB MD FRCP

Professor in Child Health
Academic Division of Child Health
(University of Nottingham)
The Medical School
Derbyshire Children's Hospital
Derby, UK

N M P CLARKE CHM FRCS

Professor and Consultant Orthopaedic Surgeon
University of Southampton and University Hospital
Southampton NHS Foundation Trust
Southampton General Hospital
Southampton, UK

TIM COLE PHD SCD HONFRCPCH FMEDSCI

Professor of Medical Statistics
MRC Centre of Epidemiology for Child Health
UCL Institute of Child Health
London, UK

SHARON CONROY BPHARM MRPHARMS PHD

Lecturer in Paediatric Clinical Pharmacy
Academic Division of Child Health, University of Nottingham
The Medical School
Derbyshire Children's at the Royal Derby Hospital
Derby, UK

CHRISTOPHER J DARE BSC BM FRCS

Consultant in Paediatric and Spinal Surgery
University Hospital Southampton NHS Foundation Trust
Wessex Neurological Centre
Southampton General Hospital
Southampton, UK

MARK DAVENPORT FRCS

Consultant Pediatric Surgeon
King's College Hospital
London, UK

MARK DENBOW PHD MRCOG

Consultant in Fetal Medicine and Obstetrics
St Michael's Hospital
University Hospitals Bristol NHS Foundation Trust
Bristol, UK

LEIGH DYET MBBS BMEDSCI MRCPCH PHD

Consultant in Neonatal Medicine
University College London Hospital NHS Trust
London, UK

D KEITH EDMONDS MBCH FRCOG FRANZCOG

Consultant Obstetrician and Gynaecologist
Department of Obstetrics and Gynaecology
Queen Charlotte's & Chelsea Hospital
London, UK

KATE FARRER FRCPC

Consultant Neonatologist
Addenbrooke's Hospital
Cambridge, UK

MARY FEWTRELL MD FRCPC

Reader in Childhood Nutrition & Honorary Consultant
Paediatrician
Childhood Nutrition Research Centre
UCL Institute of Child Health
London, UK

BRIAN FLECK BSC (HONS) MBCHB MD FRCS(ED) FRCOPH

Consultant Ophthalmologist
Eye Pavilion
Edinburgh, UK

GRENVILLE F FOX MB CHB FRCPCH

Consultant Neonatologist
Evelina Children's Hospital Neonatal Unit
St Thomas' Hospital
London, UK

ANDREW R GENNERY MD MRCP FRCPCH DCH DIP.MED.SCI

Clinical Reader/Honorary Consultant in Paediatric
Immunology & HSCT
Children's Bone Marrow Transplant Unit
Great North Children's Hospital
Newcastle upon Tyne, UK

ANDREW GREEN MB PHD FRPI FFPATH(RCPI)

Professor of Medical Genetics
Our Lady's Children's Hospital
Dublin, Ireland

ANNE GREENOUGH MD FRCP FRCPCH DCH

Professor of Neonatology and Clinical Respiratory Physiology
Division of Asthma Allergy and Lung Biology
MRC-Asthma UK Centre in Allergic Mechanisms of Asthma
King's College London
London, UK

FLORIS GROENENDAAL MD PHD

Consultant Neonatologist
Department of Neonatology
Wilhelmina Children's Hospital
University Medical Centre Utrecht
Utrecht, The Netherlands

NEDIM HADŽIĆ MD MSC FRCPCH

Consultant and Honorary Reader in Paediatric Hepatology
Paediatric Liver Service
Department of Child Health
King's College Hospital
London, UK

CORNELIA HAGMANN MD PHD

Consultant in Neonatal Medicine
Clinic of Neonatology
University Hospital of Zurich
Zurich, Switzerland

SIMON HANNAM BSC MD MRCP FRCPCH

Consultant and Honorary Senior Lecturer in Neonatology
Children Nationwide Neonatal Unit
Newborn Unit
King's College Hospital
London, UK

SIAN HARDING MBBS FRCP

Consultant Neonatologist
Neonatal Service
University College London Hospitals NHS Trust
London, UK

JANE HAWDON MA MBBS MRCP FRCPCH PHD

Consultant Neonatologist
Elizabeth Garrett Anderson Wing
University College London Hospitals NHS Foundation Trust
London, UK

ANGELA HUERTAS-CEBALLOS MD MSC FRCPCH

Consultant Neonatologist with Special interest in
Neurodevelopment
Elizabeth Garrett Anderson Wing
University College London Hospital NHS Foundation Trust
London, UK

PAUL HUMPHRIES MRCP FRCR

Consultant Paediatric Radiologist
University College London Hospital and Great Ormond Street
Hospital for Children Foundation Trusts
Honorary Senior Lecturer
Institute of Child Health
University College London
London, UK

DAVID ISAACS MBBCHIR MD FRACP FRCPCH

Clinical Professor of Paediatric Infectious Diseases
Department of Infectious Diseases and Microbiology
Children's Hospital at Westmead
Westmead, NSW, Australia

N KEVIN IVES MA MB BCHIR DCH MRCP FRCPCH MD

Honorary Senior Clinical Lecturer
Department of Paediatrics
University of Oxford
Consultant Neonatologist
John Radcliffe Hospital
Oxford, UK

ANOO JAIN FRCPCH MRCP(Ire) DM

Consultant in Neonatal Medicine
University Hospital Bristol NHS Foundation Trust
Regional Intensive Care Nursery
St Michaels Hospital
Bristol, UK

SAMANTHA JOHNSON PHD CPSYCHOL

Department of Health Sciences
University of Leicester
Leicester, UK

SIMON A JONES MB CHB BSC MRCPCH

Consultant in Paediatric Inherited Metabolic Disease
Genetic Medicine
Manchester Academic Health Science Centre
University of Manchester
Central Manchester University Hospitals NHS Foundation
Trust
St Mary's Hospital
Manchester, UK

STEVE KEMPLEY MA FRCP FRCPCH

Clinical Senior Lecturer in Paediatrics and Honorary
Consultant Neonatologist
Neonatal Transfer Service for London
Barts and the London School of Medicine and Dentistry
London, UK

GILLIAN KENNEDY MSC MRCSLT

Consultant Speech and Language Therapist
NIDCAP Trainer
Neonatal Unit
Elizabeth Garrett Anderson Wing
University College London Hospital NHS Trust
London, UK

PIPPA KYLE MD FRCOG FRANZCOG CMFM

Consultant Obstetrician, Subspecialist Maternal and
Fetal Medicine
Women's Services Directorate
Guy's and St Thomas NHS Foundation Trust
London, UK

IAN A LAING MD D UNIV FRCPE FRCPCH

Consultant Neonatologist
Neonatal Unit
Simpson Centre for Reproductive Health
Royal Infirmary of Edinburgh
Edinburgh, UK

CASSIE LAWN MBBS DRCOG MRCGP MRCPCH

Consultant Neonatologist
Trevor Mann Baby Unit
Royal Sussex County Hospital
Brighton, UK

BERTIE LEIGH HON FRCPCH FRCOG AD EUNDEM

Solicitor and Senior Partner
Hempsons
London, UK

ALAN LUCAS MD FRCPCH

Professor
Childhood Nutrition Research Centre
UCL Institute of Child Health
London, UK

Preface

This Fifth Edition of the *Textbook of Neonatology* will be a Silver Jubilee Edition, because it is now 25 years since the First Edition was published in 1986. I have renamed the book *Rennie and Robertson's Textbook of Neonatology* to reflect both the contribution made by Cliff Robertson in establishing the work as a standard text, and my own efforts in keeping it going over the last few editions. My consultant career has spanned those years, and the book has been a constant friend and companion to me during that time. I rely on the content for dependable advice or to start a literature search from a key reference, and I hope that the next generation of neonatologists and neonatal nurses will develop the same loyalty because they too find it indispensable. To that end, I am delighted that this edition will be available on the Web via the Expert Consult site. This will make it possible to keep the bulky copy of the book at home, yet access all the content from anywhere in the world via the internet.

As ever, the preparation of this edition has taken longer than anticipated, and so far it has proved impossible to achieve a

gestation period of less than six years between updates. I am glad to report that the UCLH copy of the book is worn out and dog-eared, and whilst that tells me that a new edition is long overdue it also cheers me that the book has been so well used. In the years since the fourth Edition was prepared knowledge has continued to advance at a rapid and sometimes giddy pace, and I am grateful to all the contributors for teaching me much about topics which are outside my particular field of expertise. Reading, checking and re-reading the submissions has been an enjoyable and educational experience. I hope others will find the content equally rewarding, as they continue on their paths to individual learning and in striving to deliver excellent care to the newborn baby.

Acknowledgements

Almost six years have passed since I contemplated the acknowledgements for the Fourth edition, but the number of people to thank remains formidable; far too many to name individually. At Elsevier, Nani Clansey has been wonderful, working tirelessly at reminding those authors who were slipping behind with their chapters, maintaining a grip of vast numbers of illustrations, and sorting muddled reference lists. Without her, the book would probably never have been completed at all. Thanks are also due to Michael Houston, Poppy Garraway, Kirsten Lowson, Emma Cole, Alex Jones and Annie Victor at Elsevier for their support.

As ever, it is the authors of the individual chapters who deserve the most praise. All those who write chapters for textbooks know only too well that the first blush of enthusiasm at being asked to contribute rapidly fades into irritation as the deadline looms, and ends in a phase of frenetic writing and sleepless nights once the actual task of organising the advances in knowledge into a readable piece begins. My requests to squeeze in new information whilst paring down the already minimal word counts, update all the illustrations, use colour, and keep the coverage comprehensive were met with calm, capable professionalism and amused tolerance. I can only imagine the expletives from families and friends, knowing that my suggestions must have incurred significant erosions into the already limited disposable time of busy clinicians.

Some of the original content is now historical, and to reflect that this is the first edition to have a whole chapter devoted to the history

of neonatal care. Particular thanks are due to Professor Malcolm Chiswick for taking this on, and for producing such a wonderful and readable account. In short, I cannot thank the contributors enough, and I take this opportunity to thank their partners, families, friends and secretaries on their behalf. I hope they will be pleased with the end product. My colleagues at University College Hospital London have not only put up with my commitment to the book, but they have also contributed chapters, told me of interesting cases, and continued to stimulate my interest in the fascinating world of neonatal medicine. To them, and to Gemma Birchenough our PA, special thanks are due.

Thanks are also due to all the parents who have given permission for images of their baby (or babies) to appear in the book; in particular Bernadette Brent and Alyssa Dale who allowed me to use images of their children on the cover.

Once more, I owe an enormous debt of gratitude to my husband Ian Watts. He has remained supportive and wholly encouraging throughout the many anti-social hours of work involved in editing this Fifth edition, in spite of knowing from bitter experience (based on several previous editions) that it would take far longer than I estimated at the start. I dedicate the book to him, with all my love.

Introduction

To set the scene, this chapter defines the epidemiological measures and rates relevant to neonatology and how they can vary within and between populations. This includes outlining the sources of routine collected national data for the UK and Ireland and how they can be compared with those for other European countries. This paves the way for subsequent chapters which describe data collections and research specific to neonatal care.

Births and birth rates

How birth statistics are compiled

There are three main routes through which data about births are collected. These have been described in considerable detail elsewhere (Macfarlane and Mugford 2000) but a brief description and update are given here.

The most frequently used source of data on a national scale is civil registration. In the UK parents are required by law to register a birth with the local Registrar of Births, Marriages and Deaths. As well as issuing a certificate, the registrar passes the information to a central office, which maintains records and, in the past, compiled both national and local statistics. Scotland, Northern Ireland and the Republic of Ireland each have separate General Register Offices. In 1970, the General Register Office for England and Wales was merged with the Government Social Survey to form the Office of Population Censuses and Surveys (OPCS). Then, in April 1996, OPCS merged with the Central Statistical Office and the Labour Market Statistics Group of the former Department of Employment to form the Office for National Statistics, which compiles and publishes a wide range of health, social and economic statistics. In 1999, the Office for National Statistics undertook a major review of

civil registration and proposed wide-ranging changes, including 'through-life records', but these did not get through Parliament (Office for National Statistics 2002; General Register Office 2003). On 1 April 2008, the General Register Office for England and Wales was transferred into the Home Office's Identity and Passport Service, but the Office for National Statistics continues to analyse and publish data derived from civil registration. The General Register Office for Scotland merged with the National Archives of Scotland on 1 April 2011 to become the National Records of Scotland. In Northern Ireland, the General Register Office is part of the Northern Ireland Statistics and Research Agency, which analyses and publishes the data and is itself part of the Northern Ireland Department of Finance and Personnel.

In England, Wales and Scotland, the law originally required all fetal deaths after 28 completed weeks of gestation to be registered as stillbirths. This limit was lowered to 24 weeks on 1 October 1992. All live births at any gestation have to be registered. In Northern Ireland, there is no legal requirement to register a stillbirth, but a system was set up in 1961 to enable next of kin to register them. In the Republic of Ireland there was no system for registration of stillbirths before 1995, although they have been notified to Directors of Community Care since 1957.

The second method of information collection is through birth notification. In the UK all births have to be notified to the local Director of Public Health under a system introduced in 1907 and made compulsory in 1915. This is usually done by midwives immediately after the birth, and must be done within 36 hours. The system was originally devised at an era when most births were at home, so that a health visitor could be informed and then call to see the mother and baby. From the 1960s onwards, local and health authorities developed child health computer systems on which babies' records were initiated by the birth notification and used to administer vaccination and immunisation programmes and to monitor developmental testing.

Since the introduction in England and Wales of the allocation of National Health Service (NHS) numbers for babies at birth in October 2002, the data flows have changed. As the minimum dataset associated with NHS Numbers for Babies is very limited, many maternity units continue to send the fuller dataset used previously in parallel. At the time of writing the NHS Numbers for Babies service is being moved to the NHS Spine, where it will form part of the Personal Demographics Service. In Wales, child health systems have been redeveloped so that data from birth notifications can be aggregated nationally in the National Community Child Health Database and used to produce national birth and perinatal statistics, amongst other purposes.

Despite its limitations, the NHS Numbers for Babies dataset contains key data items, notably gestational age, baby's ethnicity, time of day of birth and birth order of stillbirths as well as live births within multiple births, which are not recorded at birth registration. Following a successful pilot project, linking NHS Numbers for Babies and birth registration data for 2005, these two datasets are now linked routinely by the Office for National Statistics, enhancing the scope and range of data available at a national level (Hilder *et al.* 2007).

In Northern Ireland, each of the four Health and Social Services Boards had its own child health system. Perinatal data from these were pooled to produce data for the province as a whole, held on the Northern Ireland NHS intranet. These data are now held by the Health and Social Care Board, which superseded the four boards on 1 April 2009. In the Republic of Ireland, a subset of vital statistics data derived from the four-part birth notifications, along with data from birth and death registrations, is analysed and published centrally by the Central Statistics Office. More detailed perinatal

statistics, including clinical and sociodemographic data from the third part of the form, are analysed through the National Perinatal Reporting System and published separately by the Economic and Social Research Institute.

The third route for collecting data about births is through hospital-based systems. Traditionally these have collected data at discharge about hospital inpatient stays. More recently, systems have been developed that gather data about a person's episodes of care within a given NHS trust. NHS commissioners should hold information about care given to their residents wherever this is provided. The ways in which this is done are changing rapidly with the development of information technology systems within the NHS.

In England, information about inpatient stays in NHS hospitals is aggregated nationally through the Hospital Episode Statistics (HES) system. There is a separate Maternity HES system to collect information about women delivering in, and babies born in, the maternity departments of NHS hospitals. It should also include babies born at home or in private hospitals, but many of these records are missing. Maternity HES records include the standard admitted patient record plus a 'maternity tail', with a minimum dataset and clinical options. The items in the minimum datasets were specified by the *Steering Group on Health Services Information* (1985), chaired by Edith Körner. This was known as the Körner Committee and the datasets it recommended are usually referred to as Körner minimum datasets. The clinical options were set out in publications but were never implemented at a national level.

The HES system started in April 1987 and Maternity HES finally got under way in September 1988, but in the mid-1990s it was still very incomplete. By the financial year 1994–95 the system contained maternity tail records for only 67% of deliveries in England (House of Commons Health Committee 1996) and 72% in 2002–3 (Department of Health 2004). By 2009–10, after several years of improvement, data were submitted for between 80% and 90% of the items in the maternity tail. Data from the system are published annually on the Information Centre for Health and Social Care's website (Information Centre for Health and Social Care 2011a). Data are still missing for some units, either because they do not have a computer system in their maternity unit or because maternity systems are not linked to other systems in the hospital so the data in them do not reach Maternity HES (Kenney and Macfarlane 1999). Major changes in data collection have taken place in recent years, with the implementation of the National Care Records Service for individual patient records and of its Secondary Uses Service (Information Centre for Health and Social Care 2011b).

The NHS Information Centre has developed an ambitious new maternity secondary uses dataset for England, with over 1000 data items. It was planned to implement it in stages, with the first starting on 1 April 2011, but the start was delayed by funding decisions (Information Standards Board 2011, Child and Maternal Health Observatory, 2011).

In Wales and Northern Ireland, systems similar to Maternity HES were introduced but very few delivery records have data in the maternity tail. Analyses of data about method of delivery and length of stay have been derived from the Patient Episode Database Wales and published in bulletins on paper and on the Statistics Wales website (Health Statistics Wales 2011). As described above, the dearth of data from maternity tails has led to decisions to use child health systems for collecting more detailed maternity data in Wales.

In England data about episodes of care in neonatal intensive care units are collected, along with data about other episodes in paediatric departments, in the main part of HES. Unfortunately, these data are not routinely linked, at national level at least, to the record of the baby's delivery, but the allocation of NHS numbers to

babies at birth may make this possible in the future. There is also a lack of consistency in recording levels of special and intensive care in HES and these data are not published routinely. To address this problem a Neonatal Critical Care Minimum Dataset was defined (Information Standards Board 2006). This is described in Chapter 2.

Scotland has had a maternity information system working nationally since the mid-1970s and data about mothers have been collected through the SMR2 Maternity Discharge Sheet. In the past, data about babies were collected through the SMR11 record, which from 1996 covered only sick babies, but this has been superseded by the Scottish Birth Record, described below. Data from SMR2 are published annually in *Scottish Health Statistics*, now published electronically on the Information and Statistics Division Scotland website (Information and Statistics Division 2011a). Data from SMR2 are also combined with those from the Scottish Perinatal and Infant Mortality Survey and published annually on the Information and Statistics Division website in the *Scottish Perinatal and Infant Mortality and Morbidity Report* (Information and Statistics Division 2011b). The report has been administered by a number of different bodies over time. Since 2008, this has been the Reproductive Health Programme of NHS Quality Improvement Scotland, with oversight by the Scottish Perinatal Mortality and Morbidity Review Advisory Group. The report also contains data about the incidence of selected congenital anomalies. The website also has reports on trends over time on topics such as multiple birth and operative vaginal deliveries (Information and Statistics Division 1997, 1998, 2003).

In 2003 Scotland started to implement a completely new system, the Scottish Child Health Information Development project. The first step in this was to implement a web-based Scottish Birth Record and an electronic woman-held record with the later aim of developing links with other systems. The Scottish Birth Record system is a live database, with data entered directly by NHS staff, interfacing with hospital systems where feasible, and available to appropriate NHS staff and to parents.

The other three countries of the UK include data about neonatal care in statistics collected about activity in paediatric departments, but have not so far been able to identify them separately in published data. This gap has led to the implementation of dedicated neonatal systems, linked to the establishment of neonatal networks. The information from them is used in the neonatal audits described in Chapter 2. The Neonatal Data Analysis Unit was set up to oversee these systems and analyse the data.

Trends and variations in birth rates

Definitions

- General fertility rate: the number of live births per 1000 women aged 15–44 years living in the same area.
- Age-specific fertility rate: the number of live births to mothers of each age group per 1000 women in the age group in the same population.
- Total fertility rate: the average number of live children that a group of women would have if they experienced the age-specific fertility rates of the calendar year in question throughout their childbearing lives.

The numbers of live births registered in recent years in each of the four countries of the UK and in the Republic of Ireland are shown in Table 1.1. This shows that, in the late 1980s, the numbers of births rose everywhere except in the Republic of Ireland, before falling again in the early 1990s. After a slight increase in the mid-1990s followed by a further decline, numbers started to rise in 2002 and

2003. This rise continued until 2008, with a slight falling off in 2009, except in the Republic of Ireland. These figures are useful as a measure of the workload of the maternity and paediatric services but shed very little light on the reasons for the increases and decreases. Fluctuations can arise either as a result of changes in the size and age structure of the childbearing population or as a consequence of changes in the birth rate within each age group.

One of the most long-standing measures of birth rate is the general fertility rate. In this the number of live births is expressed as a rate per 1000 women aged 15–44 or, in some cases, 15–49 years. Figure 1.1 shows the general fertility rate for England and Wales since 1838, the first full year after civil registration began in July 1837. The rates for the mid-19th century are probably an underestimate, as birth registration did not become compulsory in England and Wales until 1874. Shortly after this the fertility rate began to decline, a trend that continued steadily until the 1930s. This was interrupted only by a trough during the First World War and a short-lived peak after the war ended. A similar peak followed the Second World War. After this there was a longer term rise in the 1950s and 1960s, followed by a decline through most of the 1970s. After the rate reached a minimum in 1977 it fluctuated, gradually increasing in the late 1980s and decreasing through the 1990s. After rising from 2003 to 2008, it fell slightly in 2009 but rose again in 2010, except for women aged under 20.

This overall rate masks changes since 1977 within age groups. Rates for England and Wales are set out in Table 1.2, which shows birth rates among women in their late teens and 20s rising slightly in the late 1980s as the ‘bulge’ of women born in the mid-1960s entered the childbearing age range (Craig 1997) and then falling through the 1990s and the early years of the 21st century. In contrast, rates among women in their early 30s rose before levelling off in the mid-1990s, while rates for women in their late 30s and 40s have risen consistently. Since 2003, rates have risen in all age groups except for women aged under 20. They declined in 2009 for all groups aged under 30 while in 2010, they rose for all age groups except women aged under 20.

These age-specific rates can be summed up in a statistic called the ‘total fertility rate’. This is a standardised measure that gives the total number of children who would be born to each woman if she experienced the age-specific fertility rates for the year in question throughout her childbearing life. As Table 1.2 shows, the rate for England and Wales rose gradually in the latter half of the 1980s, before falling gradually again, followed by a rise from 2003 to 2008 which tailed off in 2009. Age-specific fertility rates for women aged 30 and over continued to rise in 2009, while those for women aged under 30 fell slightly. Figure 1.2 shows trends over time in total fertility rates in England and Wales, Scotland and the two parts of Ireland, with Scotland having the lowest rates. Rates for local areas, published in national statistical publications for Scotland and Northern Ireland and in the Office for National Statistics Vital Statistics (VS) tables for England, vary considerably between regions and areas. Trends for each local authority area in England can also be seen in interactive maps on the Office for National Statistics website (Office for National Statistics 2011a).

For planning services it would be useful to have some idea of future trends in births, but these are notoriously difficult to predict. Nevertheless, government statisticians attempt to make such projections, combining analyses of past trends with replies to surveys about people’s intentions to have children. Population projections for the countries of the UK, formerly produced by the Government Actuary’s Department, are now produced by the Office for National Statistics. The 2008-based projections, published in 2010, assumed a peak in fertility in 2008, followed by a fall in 2009 and succeeding years and then a levelling off (Wright 2010).

Table 1.1 Live births in England, Wales, Scotland and Ireland 1975–2010

YEAR	ENGLAND	WALES	ENGLAND AND WALES*	SCOTLAND	NORTHERN IRELAND†	REPUBLIC OF IRELAND

The incidence of preterm birth and low birthweight

Definitions

- Birthweight: the first weight of the newborn or fetus obtained after birth. The actual weight should be recorded to the degree of accuracy to which it is measured.
- Low birthweight: less than 2500 g (up to and including 2499 g).
- Very low birthweight: less than 1500 g (up to and including 1499 g).
- Extremely low birthweight: less than 1000 g (up to and including 999 g).
- Gestational age: the duration of gestation is measured from the first day of the last normal menstrual period. Gestational age is expressed in completed days or completed weeks.
- Preterm: less than 37 completed weeks or 259 completed days of gestation.

In England and Wales, birthweight data have been collected since the mid-1950s through the birth notification system. From 1953 to 1973, each local authority, and from 1974 to 1986 each health authority, submitted a form to central government giving the numbers of low-weight births to women living in their area. Data from this source have been used for these years in [Figure 1.3](#), which shows that the percentage of liveborn babies weighing 2500 g and less, the original definition of 'low birthweight', remained at a similar level of between 6% and 7% from the mid-1950s to the mid-1980s.

The system changed in the early 1980s, when arrangements were made for health authorities to extract birthweights from babies' birth notifications and send them to local registrars of births and deaths to be added to the birth registration. Data flows started to change from 2006 onwards when local register offices moved to registration online. This was an intermittent process, with many teething problems, which could have affected data quality. By July 2009, it was implemented in all register offices in England and Wales. A byproduct of this is that birthweight is now passed

Fig. 1.1 General fertility rate, England and Wales, 1838–2010. (Data from Office for National Statistics, *Birth Statistics*.)

Fig. 1.2 Total fertility rates, UK and Ireland, 1938–2010. (Data from Office for National Statistics, General Register Office Scotland, Northern Ireland Statistics and Research Agency and Central Statistics Office, Ireland.)

electronically to the Office for National Statistics from the notification by the midwife or doctor in attendance at the birth.

These data are analysed using the current definition of low birthweight, which was changed in the ninth revision of the *International Classification of Diseases* (World Health Organization 1977) to

‘under 2500 g’. Babies weighing under 1500 g at birth are now categorised as ‘very low birthweight’, and those weighing under 1000 g are described as ‘extremely low birthweight’ (World Health Organization 1992). These birthweight groups are used in Table 1.3 and in the data for the mid-1990s onwards in Figure 1.3.

Table 1.2 Age-specific fertility rates, England and Wales, 1964–2010

YEAR	LIVE BIRTHS	LIVE BIRTHS PER 1000 WOMEN IN AGE GROUP								TOTAL FERTILITY RATE
		15–44	Under 20	20–24	25–29	30–34	35–39	40–44	45 and over	
1964 (max.)	875 972	92.9	42.5	181.6	187.3	107.7	49.8	13.0	0.9	2.9
1977 (min.)	569 259	58.1	29.4	103.7	117.5	58.6	18.2	4.1	0.3	1.7
1979	638 028	63.3	30.3	111.3	131.2	69.0	21.3	4.3	0.4	1.8
1985	656 417	61.0	29.5	94.5	127.6	76.4	24.1	4.6	0.4	1.8
1990	706 140	64.3	33.3	91.7	122.4	87.3	31.2	5.0	0.3	1.84

(Data from Office for National Statistics, Mortality statistics, Series DH3 and Childhood mortality.)

Interpreting trends

Both show recent trends in the incidence of low birthweight in England and Wales. Although the percentage of liveborn babies weighing under 2500 g has fluctuated since 1983, the general trend was upwards, followed by a levelling off from 2000 onwards, followed by an apparent drop in 2007. This could be a discontinuity

resulting from the change of method of data collection. There were similar patterns in all groups of babies weighing under 2000 g, except that, in the under-1000-g group, the discontinuity in 2007 took the form of an increase.

Between 1983 and 1988 there was no clear trend in the very small proportion of liveborn babies for whom birthweight was missing, and who are known to include a high proportion of small and

Fig. 1.4 Percentage of live births born before 37 weeks of gestation, by multiplicity, Scotland, 1976–2010. (Data from Information and Statistics Division Births in Scottish Hospitals.)

immature babies (Alberman and Botting 1991). In the middle of 1989, financial constraints in the OPCS led to a decline in the completeness of recording of birthweight on birth registration records. Birthweight was missing on up to 4% of records from 1989 to 1994, making the data for these years difficult to interpret. As shown later in Table 1.18, the mortality rate among babies with missing birthweights was well above the overall rate, suggesting that the group included a relatively high proportion of low-birthweight babies. By 1995, the numbers of missing birthweights had declined markedly and the data for 1995 onwards used in Tables 1.3, 1.9, 1.11, 1.13 and 1.18 (see below) and Figure 1.3 became much more reliable than those for the early 1990s. Unfortunately, however, the move to registration online was accompanied by a slight increase in the percentage of missing birthweights, from under 0.2% between 2000 and 2004 to 1.1% in 2007 and 0.74% in 2009.

The reported incidence of low-weight births in 1995 was well above that for 1988 and rose markedly after 1995, as Figure 1.3 shows. Analyses of birthweight data for both England and Wales and Scotland identified two separate trends, however. Although the percentages of low-weight births had increased during the 1980s, there had also been an increase in the proportion of heavier babies (Power 1994; Bonelli and Raab 1997; Maher and Macfarlane 2004). From the 1990s onwards in England and Wales, the proportion of heavier babies levelled off, fluctuating between 11.3% and 11.6% for singleton births.

Although the World Health Organization has published a definition of preterm birth, it has no definition of very preterm or extremely preterm, as a result of the lack of consensus mentioned in Chapter 2. It does, however, recommend groups to be used when publishing data about gestational age. These are under 28, 28–31, 32–36, 37–41 and 42 or more completed weeks and the corresponding numbers of days (World Health Organization 1992). The under-28-week category is often subdivided into less than 24 and 24–27 completed weeks, as has been done in this chapter.

When OPCS made the arrangements in the 1970s to acquire the information about babies' birthweights from birth notification, it also requested gestational age. For reasons that are long forgotten, access to this was refused by clinical organisations. Data about gestational age of babies born in England and Wales only became available at a national level in England and Wales for 2005 onwards via the linkage with NHS Numbers for Babies data (Moser et al. 2007; Hilder and Moser 2008). The data available so far are summarised in Table 1.4 and are published in fuller detail in *Health Statistics Quarterly* and elsewhere on the Office for National Statistics website (Moser et al. 2007, 2008; Moser 2009). As a result, the only data about long-term trends in preterm birth are for Scotland (Macfarlane et al. 1988; Information and Statistics Division Scotland 1997, 2011a; Macfarlane and Mugford 2000). A reported increase in the proportion of preterm births in Scotland can be seen in Figure 1.4 and Table 1.5, which are derived from information in the SMR2 system. Although multiple births have contributed to the rise, preterm singleton births have also increased since the mid-1970s as a proportion of all live births. Table 1.5 also shows a decrease in the rate of postterm births in Scotland and comparison with Table 1.4 suggests that this rate is lower than in England and Wales.

The data for both England and Wales and Scotland suggest that there has been an increase in the reported incidence of very small and very preterm babies. Although the rising incidence of multiple birth, discussed later, has made a major contribution to this rise, it is certainly not the only factor. It has been suggested that an increasing tendency to admit smaller and iller babies to neonatal nurseries has also contributed to the rise. By law all live births should be registered but there is a subjective element in distinguishing between a live birth and a miscarriage, particularly if the baby dies very shortly after birth. In the past some of these very tiny babies would have been regarded as miscarriages and would not therefore have been registered as live births. The lowering of the gestational age

limit for registering fetal deaths as stillbirths in all countries of the UK in October 1992 may well have reinforced changes in people's perceptions of which births should be registered as live births.

Another factor that may have contributed to the increase in registration is the growing recognition of parents' need to mourn an unsuccessful outcome of pregnancy. The formalities of registration can sometimes form part of this, together with the process of holding a funeral.

Interpreting differences between areas and countries

The incidence of low birthweight varies both between geographical areas and between sectors of the population, including internationally. Considerable differences were seen in the late 1980s between the countries and parts of countries that took part in the International Collaborative Effort on birthweight, plurality and perinatal and infant mortality (Hartford 1990). Similar differences were seen in the incidences of low birthweight in 1990 (Masuy-Stroobant

1996), in the Peristat perinatal indicator project which used data for the years around 2000 (Buitendijk et al. 2003), and again in the Europeristat project using data for 2004, shown in Table 1.6 and Figure 1.5 (Europeristat 2008). These studies used data collected routinely through the participating countries' vital statistics systems or medical birth registers (Zeitlin et al. 2003; Macfarlane et al. 2003; Gissler et al. 2010).

Although the overall incidence of low birthweight in a population tends to be a reflection of the health of that population in general, and of women of childbearing age in particular, at the bottom end of the birthweight range it is affected by the country's criteria for birth registration. In theory this should not affect live births, as in most countries a live birth is registrable regardless of gestational age or birthweight. There are, however, considerable variations in the criteria for the registration of late fetal deaths as stillbirths. The differences within Europe can be found in Table 3.1 of the Europeristat report (Europeristat 2008). Many countries, including those in the UK, do not follow the World Health Organization's recommendation to use a 22-week cut-off.

P, provisional. (Data from Information and Statistics Division Births in Scottish Hospitals.) Notes: 1. Excludes home births and births at non-National Health Service hospitals. 2. Where four or more babies are involved in a pregnancy, birth details are recorded only for the first three babies delivered. 3. 2010 data are provisional. 4. Includes births where the birthweight is unknown.							

Inevitably, these wide differences in the gestational age at which fetal deaths are registrable as stillbirths can affect decisions about whether a very preterm birth should be regarded as a registrable live birth or as a miscarriage, although the extent to which they do so appears to vary from country to country. As a result, in the Europeristat study, the percentage of live births weighing under 500 g ranged from 0.00% in many countries to 0.05% in Germany and 0.06% in England and Wales. Although these differences have a very limited impact on the comparability of statistics about low birthweight, they have a much larger impact on the comparability of mortality statistics (Buitendijk et al. 2003; Mohangoo et al. 2011). To deal with this problem, the World Health Organization recommends that babies weighing under 500 g or born before 22 completed weeks of gestation are excluded from comparative statistics (World Health Organization 1992). In the Euronatal study, with data for the mid-1990s and common cut-offs, the differences between countries changed when common cut-offs were applied (Graafmans et al. 2001, 2002).

A further factor that has to be taken into account is the extent to which data about gestational age and birthweight are missing, either because the information was not recorded initially or because it was

not passed on to population-based data collection systems. This is likely to have affected the trends shown in Figures 1.3 and 1.4, as well as comparisons between countries. Furthermore, where data are almost complete, birthweight is most likely to go unrecorded for babies who die very soon after birth.

Real differences in the low-birthweight rates within countries with the same or similar data collection systems are shown in Table 1.7. In 2009, the incidence of low-weight births in the Government Office regions of England ranged from 6.4% in the South-west region to 8.5% in the West Midlands region. Each of these regions includes a variety of different populations. Differences between local authorities are great. Even though these small babies make up a tiny proportion of all births, they make a considerable contribution to mortality rates. Comparing the countries of the UK, the incidences of low-weight and very-low-weight births in Wales were lower than those for England in 2009, while those for Scotland and Northern Ireland were lower still and the lowest rate of low birthweight shown in Table 1.7 was in the Republic of Ireland.

Differences between smaller areas, such as electoral wards, are even more marked. In each of the countries of the UK, area

deprivation scores have been constructed to classify small areas. These use data from the census and other data, such as unemployment and crime rates, that can be disaggregated to a local level. They can be used to group together areas with similar characteristics within each country, but not for the whole of the UK, given that the composition of the scores is different in England, Wales, Scotland and Northern Ireland (Department of Communities and Local Government 2011).

Social class differences

Definition

- National Statistics Socio-economic class (Table 1.8).

Differences between geographical areas in the incidence of low birthweight reflect, in their turn, differences in the characteristics of the populations and differences between groups within the

population. Table 1.9 shows differences in the incidence of low birthweight in England and Wales when live births are tabulated by the baby's father's social class. The classes used are the eight-class version of the National Statistics Socio-economic classes. The three-, five- and eight-class versions shown in Table 1.8 have been used since 2001, and were modified in 2010 using the Standard Occupational Classification, as revised for use in the 2011 Census (Office for National Statistics 2010). They supersede the Registrar General's social classes, which were used during the 20th century (Macfarlane and Mugford 2000; Rowan 2003).

For babies in each group, and for all birthweights under 2500 g combined, the table shows clear differences between the higher rates of low birthweight among babies with fathers in routine and semiroutine occupation and the lower rates among babies with fathers in professional and managerial occupations. Rates were highest among sole registrations, babies registered by their mother alone. Ideally, these data and those in Table 1.7 should be restricted to singleton births because the birthweight distribution for multiple births is different.

Since 1986, mothers have had the option of recording their occupation on their baby's birth certificate but many mothers still do not do so, either because they are not in paid employment or, in the case of the youngest women, because they do not yet have an occupation. For this reason, tabulations by mother's social class are not routinely published (Macfarlane and Mugford 2000; Rowan 2003).

In Scotland, an analysis of births in the years 1980–4 showed a clear social class gradient in the incidence of preterm births at 20–27, 28–31 and 32–36 weeks (Information and Statistics Division 1987; Macfarlane et al. 1988). In this case, the gestational ages of babies born within marriage were tabulated according to their father's social class, and births outside marriage were grouped into a single category. An analysis of data for the early 1990s, which extended this to include analyses of low birthweight and preterm birth among births outside marriage by mother's social class, found social class differences in low birthweight but not in preterm birth (Macfarlane and Mugford 2000). A subsequent analysis of social class differences in adverse perinatal outcomes, including low

birthweight, preterm birth and small for gestational age, in Scotland found that, although differences narrowed during the 1980s, they widened during the 1990s (Fairley and Leyland 2006).

Published analyses of data on preterm birth in England and Wales have used the less detailed three-class version of the National Statistics Socio-economic classes. These data, shown in Table 1.10, also show that preterm birth rates are higher in the less advantaged socio-economic groups, except among births before 24 weeks. They are also tabulated by type of registration and show similarities between the rates for births to married parents and births to parents who are not married but give the same address when registering their baby. In contrast, rates for unmarried parents who give different addresses are similar to those for sole registrations. This highlights the differences within the growing category of births outside marriage.

Ethnic origin and country of birth

Birthweight and gestational age distributions are known to differ between ethnic and racial groups (Parsons et al. 1993;

Macfarlane and Mugford 2000; Gagnon et al. 2009; Urquia et al. 2010).

At the time of writing, ethnic origin is not recorded at birth registration, but service users' self-reported ethnicity should be recorded in national NHS data collection systems. Although mothers' ethnic origins had been recorded on most hospital notes and on some districts' birth notification forms for some years, the way it was recorded and classified varied widely. In the mid-1990s, it was decided that the definitions used in the 1991 census should be used universally (National Health Service, Department of Health 1990a, b). These were superseded by the revised classifications used in the 2001 census and will subsequently be replaced by the categories used in 2011. In some cases, the data are incomplete and of questionable quality. Although data on birthweight and method of delivery, collected through the Maternity HES, have been published, black and Asian groups were aggregated in an attempt to overcome problems with data quality, but this obscures known differences within them (Department of Health 2004).

The 1991 population census was the first in which people were asked to indicate how they described their ethnic origin. The

categories used in the question were: white, black–Caribbean, black–African, black–other, Indian, Pakistani, Bangladeshi, Chinese, and any other ethnic group. People descended from more than one ethnic or racial group were asked to tick the one to which they considered they belonged, or to tick the ‘any other ethnic group’ box and describe their ancestry (Office of Population Censuses and Surveys and General Register Office, Scotland 1989). This classification has been criticised on the grounds that it is more an indicator of skin colour than of cultural and social identity (Ahmad and Sheldon 1992).

These questions were revised for use in the 2001 census, when slightly different questions were asked in each of the countries of the UK. In England and Wales, specific categories for people of mixed ethnic background were added, along with the terms black British and Asian British, while Scotland added black Scottish and Asian Scottish categories. The Office for National Statistics has subsequently revised its categories further for use in the 2011 census, in the light of further criticisms, and added a question about national identity within the UK (Office for National Statistics 2003, 2009). In addition, in 2001 and 2011, questions on religion, previously asked only in Northern Ireland, were added in England, Wales and Scotland, where they focused particularly on religions practised by minority ethnic groups.

The ethnic origins of parents are not recorded at birth and infant death registration in England and Wales but their countries of birth are recorded. Although not a measure of ethnic origin, as many women in some minority ethnic groups having babies in the UK today were themselves born in the UK and some were born in other countries to which their parents migrated, it is an approximate measure of migration status. Table 1.11 gives some insight into the differences in the incidence of low birthweight in 2009. As in other years and in particular in an analysis of data for the years 1983–2000, it was highest among babies with mothers born in Pakistan, India and Bangladesh, and nearly as high among babies whose mothers were born in the Caribbean Commonwealth, East Africa and the ‘rest of Africa’, which is predominantly West Africa. In contrast, the incidence of very low birthweight was markedly higher among babies whose mothers were born in the Caribbean Commonwealth and the ‘rest of Africa’ (Collingwood Bakeo 2004). For data about births from 2010 onwards, the Office for National Statistics has adopted a new country of birth classification, which is not tied to membership of the British Commonwealth.

The data items recorded on NHS Numbers for Babies notifications include ‘baby’s ethnicity’. This is somewhat problematic, given that it should be self-reported, but the linkage of this dataset to birth registration has given the opportunity to compare this with the parents’ countries of birth. Further linkage with Maternity HES has now enabled comparison with the mother’s ethnic origin (Dattani, Datta-Nemdharry and Macfarlane, 2011 and 2012). Analyses of birthweights of babies reported as being of South Asian ethnicities has found little difference in the mean birthweights of those whose mothers were born in the UK and those born in their countries of origin (Leon and Moser 2010). A further analysis has found similarities between rates of preterm birth of babies of Caribbean ethnicity according to whether their mothers were born in the Caribbean or the UK and that, for babies of African ethnicity, rates were similarly high for those whose mothers were born in Western or Middle Africa compared with those whose mothers were born in other parts of Africa (Datta-Nemdharry et al. 2011). This is consistent with the results of studies in the West Midlands, East London, St Denis in northern Paris and with the high rates seen in black women in the USA (Aveyard et al. 2002; Zeitlin et al. 2004; Macfarlane et al. 2005, Goldenberg et al. 2008).

Mother’s age

Rates of low birthweight are highest among babies born to women aged under 20 and to women in their 40s and lowest for mothers aged 25–34, as Table 1.12 shows, and rates of preterm birth show a similar but less marked pattern (Moser 2009). The favourable outcome for women in their early 30s is to some extent a consequence of social class differences in childbearing. Although there is a tendency in the population as a whole, both in the UK and in other developed countries, to defer childbearing, women in less skilled occupations are more likely to have their children in their 20s while women in professional occupations are more likely to delay childbearing until their 30s. Women in their late 30s and 40s are more likely to have multiple births and also more likely to experience fertility problems.

These data illustrate the considerable differences that exist between groups within the population in the incidence of low-birthweight and preterm birth and differences within the low-birthweight and preterm birth ranges. The association between these and differences in mortality and morbidity will be discussed later and in Chapter 3, but it is important to remember when interpreting these data that being classified as low birthweight does not necessarily imply that the baby will have clinical problems, particularly at the upper end of the low-birthweight range. On the other hand, the smaller the baby and the shorter its gestational age, the higher the risk of mortality and morbidity. Reviews of the research on the incidence of preterm birth generally conclude that the mechanisms are still poorly understood but that both adverse social conditions and infection are likely to play a part (Kramer et al. 2001; Wadhwa et al. 2001, Kramer and Hogue 2009). The clinical aspects of preterm birth are discussed in Chapter 3.

Multiple births

In England and Wales, multiple births accounted for just over a quarter of babies born alive in 2007 weighing under 1500 g, as Table 1.13 shows. After declining for many years, the incidence of multiple births, shown in Figure 1.6, started to increase from the mid-1970s onwards. The increase continued through the 1980s, from 10.1 multiple births per 1000 maternities in 1982 to 11.4 in 1989, 14.1 in 1995 and 16.2 in 2009 then fell to 15.4 in 2010. There are no data about multiple birth rates for England and Wales for 1981, as multiplicity was not recorded during this year because of industrial action by local registrars of births and deaths.

Multiple birth rates for England and Wales are compared with those for Scotland and Ireland in Table 1.14. Trends in Scotland were similar to those for England and Wales, although rates were slightly lower in Scotland up to the early 1990s. In Northern Ireland the twinning rate was already higher and did not increase in the latter half of the 1980s, but rose considerably in the early 1990s. The rates reached a similar level by the beginning of the 21st century. Since then, they have remained stable in Northern Ireland, but have continued to rise in England and Wales, Scotland and the Irish Republic.

The triplet and higher order birth rates for England and Wales, shown in Figure 1.7, present a rather more dramatic picture than that for multiple births as a whole. After rising slightly during the 1970s, the proportion of triplet and higher order births more than doubled during the 1980s, rising from 12.2 per 100 000 maternities in 1982 to 28.6 in 1989. After a slight pause it rose again sharply to 45.0 in 1995 and 48.3 in 1998, before starting to fall, reaching 21.3 in 2003 and remaining around that level. Rates for Scotland and Northern Ireland, shown in Table 1.14, followed the same

*Because of the small number of stillbirths in 'elsewhere' in the UK, all figures for this group have been combined with England and Wales to protect confidentiality.
(Data from Office for National Statistics, Birth Statistics.)

pattern although the timing differed, while rates in the Irish Republic have remained high.

The rising triplet rate was a common feature in most European countries. By 1990, the rates in Belgium and the Netherlands were the highest in Europe, followed by those in West Germany, Italy and France (Masuy-Stroobant 1996). Despite its reputation for high rates of triplet and higher order births, Australia's rate for 1994, 35.0 per 100 000 maternities, was no higher than some of these

(Australian Institute of Health and Welfare National Perinatal Statistics Unit 2003). As Table 1.15 shows, triplet rates were still higher than 0.40 per 100 000 maternities in 2004 in the Netherlands, the Brussels region of Belgium, Denmark, Germany, Spain, Italy and Hungary and very much higher among the small numbers of maternities in Cyprus and Malta (Europeristat 2008).

The rise in the incidence of multiple births in general, and triplet and higher order births in particular, is usually attributed to the

(Data from Office for National Statistics 2011, childhood mortality statistics 2009 Table 10.)

**Fig. 1.6** Multiple birth rates, England and Wales, 1938–2010. (Data from Office for National Statistics, *Birth Statistics* No data are available for 1981 following industrial action by Registers of Births, Marriages and Deaths.)

increasing use of drugs for the medical management of subfertility and, since the mid-1980s, to techniques for assisted conception. Unfortunately, there are few data available to quantify their contribution over and above the increase that will have occurred spontaneously as a result of the rising age at childbirth (Blondel and Macfarlane 2003). The National Study of Triplet and Higher-Order Births estimated that 36% of mothers of triplets and 70% of mothers of quadruplet and higher order births born in the years 1980 and 1982–5 had used drugs for the medical management of subfertility (Botting et al. 1990).

The impact of in vitro fertilisation (IVF) was negligible before 1985 (MRC Working Party 1990) but since the 1990s it has become

considerable (Human Fertilisation and Embryology Authority 2011). Statistics produced by the Human Fertilisation and Embryology Authority (1994) and its predecessor, the Interim Licensing Authority for Human In Vitro Fertilisation and Embryology (1990), show a clear association between the rise in triplet and higher order births from 1985 onwards and the increasing use of IVF, gamete intrafallopian transfers and associated procedures. Rising rates of multiple births up to the early 1990s in England and Wales coincided with the increasing use of assisted conception and prescriptions for drugs for the medical management of subfertility but the association could not be quantified as it was based solely on routinely collected data (Dunn and Macfarlane 1996). Since then,

Table 1.13 Multiple births as a percentage of all births occurring in 2007, England and Wales

BIRTHWEIGHT (G)	MULTIPLE BIRTHS AS A PERCENTAGE OF

prescribing data have been even more difficult to interpret; for example, a decline in the late 1990s may have been a shift to the private sector, about which no statistics are collected routinely, rather than a real decline in use.

The decrease in the triplet rate in the UK followed guidance from the Royal College of Obstetricians and Gynaecologists in 2000 that no more than two embryos should be replaced in IVF procedures involving women under 40. The Human Fertilisation and Embryology Authority included this in its Code of Practice, launched in January 2004. The overall rate of multiple births continued to rise, however, with just under a quarter of births following assisted conception in the UK being multiple (Human Fertilisation and Embryology Authority 2011).

The high rates of multiple births shown in Table 1.14 and in countries where IVF is practised widely led to trials of implantation of just one embryo. A meta-analysis of research on single-embryo transfer concluded that, compared with double-embryo transfer, elective single-embryo transfer resulted in a higher chance of a term singleton live birth, provided that the strategy included an additional cycle with a frozen embryo if the first cycle was unsuccessful (McLernon et al. 2010). It also found that the multiple pregnancy rate after single-embryo transfer was comparable to that in spontaneous pregnancies (McLernon et al. 2010). In the light of this, in

*Excluding 1981. [†] Based on a revised methodology to take better account of multiple births, including stillbirths. [‡] 2001 only. (Data from Office for National Statistics; General Register Offices for Scotland and Northern Ireland; and Central Statistics Office, Republic of Ireland, Vital statistics.)				

Fig. 1.7 Triplet and higher order births, England and Wales, 1938–2010. (Data from Office for National Statistics, Birth Statistics. No data are available for 1981 following industrial action by Registers of Births, Marriages and Deaths.)

January 2009 the Human Fertilisation and Embryology Authority introduced a policy to promote single-embryo transfer and minimise the risk of multiple births from IVF treatment. It started to set a maximum multiple birth rate that clinics should not exceed, with the aim of lowering it each year to attain a multiple target of 10% multiple births. It set up a dedicated system to monitor progress towards this target, with reports published on its website ([Human Fertilisation and Embryology Authority 2011](#)). It could be that these policies contributed to the fall in the multiple birth rate in England and Wales in 2010, but no definitive conclusions can be drawn from data for a single year.

Although the HFEA collects data from clinics about all relevant procedures undertaken in the UK, irrespective of whether the women concerned are resident or give birth in the UK, it points out that it does not collect data about the growing numbers of women who go abroad for IVF and then return to the UK to give birth ([Human Fertilisation and Embryology Authority 2010](#)).

Mortality in the first year of life

Definitions

- Stillbirth rate: number of stillbirths per 1000 live births and stillbirths.
- Infant mortality rate: number of deaths at age under 1 year per 1000 live births.
- Perinatal mortality rate: number of stillbirths plus number of deaths at age under 7 days per 1000 live births and stillbirths.
- Early neonatal mortality rate: number of deaths at age under 7 days per 1000 live births.
- Neonatal mortality rate: number of deaths at age under 28 days per 1000 live births.
- Postneonatal mortality rate: number of deaths at age 28 days and over, but under 1 year, per 1000 live births.

Fig. 1.8 Definition of stillbirth and infant mortality rates.

Trends in mortality rates

The classic indicators of the outcome of pregnancy are stillbirth rates and death rates during the first year of life, defined above and illustrated in [Figure 1.8](#). Trends since 1905 in neonatal and post-neonatal mortality rates for England and Wales are illustrated in [Figure 1.9](#). Although the series of infant mortality rates reaches back to the mid-19th century, the current subdivision of the first year of life into the first month and deaths at age of at least 1 month but under 1 year started in 1905. The publication of more detailed analyses started at a time when public concern about infant mortality, stemming from the unfitness of many potential recruits for the Boer War, led to a request to the General Register Office for more detailed statistics ([Tatham 1907](#)).

Whereas neonatal mortality rates have decreased relatively steadily during the 20th century, postneonatal mortality, which was initially higher, shows a different pattern. It decreased very rapidly in

Fig. 1.9 Infant mortality, England and Wales, 1905–2010. (Data from Office for National Statistics, Mortality Statistics)

Fig. 1.10 Postneonatal deaths as a percentage of infant deaths, England and Wales, 1905–2010. (Data from Office for National Statistics, Mortality Statistics.)

the first half of the century with the decline in fatality from communicable diseases. It showed signs of levelling off between the mid-1970s and mid-1980s. After virtually halving in the late 1980s and early 1990s, the rate levelled off again, before starting to fall more slowly, accounting for about a third of infant deaths, as Figure 1.10 shows.

More recent trends in infant mortality are shown in Figure 1.11, which shows early and late neonatal mortality rates separately. The impact of the change in legislation about stillbirth registration on published stillbirth and perinatal mortality rates is illustrated in

Figure 1.12. The published rates, shown with a dashed line from 1992 onwards, increased. Rates from which stillbirths at 24–27 weeks of gestation have been excluded are plotted as a continuation of the solid line. These showed an apparent halt in the downward trend, with a rise from 2001 to 2004, but subsequently started falling again.

Neonatal, postneonatal and infant mortality rates for England, Wales, Scotland and Ireland in the years since 1970 are shown in Table 1.16. These show continuing small declines in neonatal mortality through the 1990s. As in England and Wales, there was a

Fig. 1.11 Infant mortality, England and Wales, 1960–2010. (Data from Office for National Statistics, *Mortality Statistics*.)

Fig. 1.12 Stillbirth and prenatal mortality rates, England and Wales 1960–2009. (Data from Office for National Statistics, *Mortality Statistics*.)

tendency for the postneonatal mortality rate to level off in the 1980s in each of the other countries, followed by a fall in the late 1980s and from the 1990s onwards. The trends in Scotland, Wales and both parts of Ireland are less clear than those in England and Wales, as they are based on smaller numbers of deaths. As a whole, however, infant mortality continues to decline in most westernised countries, although many European countries have small numbers of deaths, because their populations are small, making trends less apparent.

To what extent do trends in infant mortality in the UK reflect changes in the relative size of high-risk groups, and to what extent has mortality fallen within these groups? Figure 1.3 shows no increase in the incidence of low birthweight in England and Wales between the mid-1950s and mid-1980s, but a rise up to the turn of the century, followed by a fall. Table 1.3 shows a similar picture,

but with an increase in the reported incidence of babies in the lowest birthweight groups, who have the highest mortality. As suggested earlier, the change in definition of stillbirth may have increased the tendency to register very preterm live births, rather than regarding them as miscarriages.

Within birthweight groups, however, trends in mortality look different. A very marked fall between 1963 and 1986 in mortality in the first week after live birth among babies weighing 2500 g and under, followed by a much less dramatic fall since the late 1980s, can be seen in Figure 1.13. A different pattern can be seen in Figure 1.14, which shows a more recent and very marked decline from the late 1970s onwards in mortality rates among babies weighing 1000 g and under, and, after definitions changed in the mid-1980s, among babies weighing under 1000 g. No data about gestational age were available at a national level through most of

this era, but the data for 2005–8, shown in Table 1.17, indicate that mortality is persistently high among babies born before 24 weeks of gestation. Figure 1.17 uses data for 2008 plotted on logarithmic scale to show how neonatal and infant mortality vary by week of gestational age.

The fuller data in Table 1.18 show that neonatal mortality continued to fall in England and Wales from the mid-1980s until the early 1990s, but from the mid-1990s onwards the decline appeared to be confined to babies weighing between 1000 and 2499 g. Trends for the larger babies are far from clear. Table 1.18 also illustrates the

impact of the increase in 1989 of the numbers of birth records with missing birthweights. Between 1983 and 1988, when very few birthweights were missing, mortality in this group was very high, suggesting that the babies might not have been weighed because they were very ill or immature.

Between 1989 and 1994 mortality in this group was lower than before, but still markedly higher than average. Thus, mortality in the groups under 2500 g is likely to have been artificially depleted over this period. In 1995, when the proportion of babies with missing birthweights was very much smaller, mortality among them rose, but not to its former level. This means that caution is needed when interpreting the trends in mortality among low-birthweight babies in the late 1980s and early 1990s, shown in Figures 1.13 and 1.14 and Table 1.18. Similar caution is needed in interpreting rates for 2007 onwards, in the light of the recent changes in data flows and increases in the extent of missing birthweights.

Table 1.19 shows neonatal mortality rates by birthweight for singleton babies without lethal anomalies born in Scotland over the years 1985–2002. These are tabulated by gestational age in Table 1.20. Neonatal mortality rates tended to decline, although there was considerable fluctuation because of the smaller numbers of babies involved.

Postneonatal mortality rates for England and Wales, given in Table 1.18, showed no sign of a decline over the years 1983–8, particularly for babies with birthweights under 2500 g. Apart from a possible increase in the 2000–2499-g group, the picture was again one of fluctuation, the extent of which is not surprising, given the relatively small numbers of deaths in each group. This was followed by a sharp decline between 1989 and 1992 in all groups, except for babies weighing under 1000 g. This pattern persisted at a lower level from the mid-1990s onwards.

Putting the neonatal and postneonatal mortality rates together to look at infant mortality as a whole, it can be seen that rates tended

to decline up until 1985 and then started to level off. After a decline over the period 1989–93, rates appeared to level off again before declining very slowly from the late 1990s onwards.

It is usual to present birthweight-specific mortality rates in 500-g groups, and mortality rates for babies born in 2007 in singleton and multiple births are compared in Figure 1.15, but there is considerable variation within these groups, particularly at the bottom end of the scale. A fuller picture could be seen of the ‘crossover’ of rates in an earlier special analysis in which infant mortality rates for the years 1983–7 combined were analysed in 100-g groups (Alberman and Botting 1991). It was necessary to combine 5 years’ data to have sufficient numbers of deaths in each group to eliminate the effects of random variation.

Social class differences

Innumerable studies over the years have shown social class gradients in stillbirth and infant mortality rates for the Registrar General’s social classes (Macfarlane 1996b; Drever and Whitehead 1997; Macfarlane and Mugford 2000; Macfarlane et al. 2004; Macintosh et al. 2006), as did routine data published annually (Oakley et al. 2009). Neonatal and postneonatal mortality rates for England and Wales, analysed by the National Statistics Socio-economic class of the baby’s father, are shown in Figure 1.17. The analysis includes

both births within marriage and those outside marriage registered jointly by both parents, who account for the majority of the rising proportion of births outside marriage. The very high mortality rates among babies registered by the mother on her own are also shown. The data are from the infant mortality-linked file of the Office for National Statistics (Office for National Statistics 2011b).

The most striking feature is that, although there are marked differences between groups, using the current classification does not produce a straightforward gradient. Unlike the Registrar General’s classification, which was based on crude assessments of the status of individual occupations, the new classification is based more firmly in sociological theory. In particular, group 4 consists of people working on their own account, who enjoy comparatively low mortality and good health, despite their lack of social status. The explanation advanced is that this results from the amount of autonomy they experience (Rose and O’Reilly 1998). When the groups are amalgamated to form the three-class version of the classification, as has been done in the revised version of the Department of Health’s infant mortality target set under the previous UK government, this distinction disappears (Rowan 2003). Another notable feature in Figure 1.17 is the difference between neonatal and post-neonatal mortality rates, with the latter showing much wider differences between classes. Deaths attributed to the sudden infant death syndrome show particularly marked social class differences, which

contribute substantially to the social class differences in postneonatal mortality (Macfarlane and Mugford 2000).

Like low-birthweight and preterm birth, infant mortality varies between babies whose parents gave the same address on their baby's birth registration and those who did not and were therefore unlikely to be living together, as Figure 1.18 shows.

Ethnic origin and country of birth

Neonatal and postneonatal mortality rates for selected mothers' countries of birth for the years 2007–9 combined are shown in Figure 1.19 and tabulated more fully in Table 1.21. As in other years, mortality rates for babies whose mothers were born in Pakistan are markedly higher than those with mothers born elsewhere in the Indian subcontinent, which are much closer to the overall level. This pattern is similar to that apparent in the 1990s, with raised

mortality rates among babies whose mothers were born in Pakistan being associated with congenital anomalies and mortality being relatively high compared with other groups right across the birth-weight range (Balarajan and Raleigh 1990). As in earlier years, mortality rates were also relatively high for babies born to women born in the Caribbean Commonwealth and the largely west African 'rest of Africa'. These groups have high mortality associated with immaturity, which is compatible with their exceptionally high proportions of very-low-birthweight babies (Collingwood Bakeo 2004). Perhaps anomalously, rates were high for babies whose mothers were born in East Africa.

Infant mortality rates by babies' recorded ethnicity are shown in Table 1.22. Here again, rates are high for babies stated to be of Pakistani origin and among those of black Caribbean origin. Babies of black African origin had infant mortality rates which were lower, but above those for other groups, reflecting the heterogeneity of this group.

Mother's age and parity

Both neonatal and postneonatal mortality rates are highest for babies born to women aged under 20 or in their 40s, as Table 1.23 shows. In the past, rates were lowest for women in their 20s, but they are now lowest for women in their early 30s. This reflects the extent to which women in the more advantaged socio-economic groups are delaying childbearing until their 30s. Although, at any age, the incidence of clinical problems and consequently mortality rates is highest among women having their first birth, there is a dearth of data on this subject for the UK as, under the Population (Statistics) Acts, in England and Wales, parity has been recorded at birth registration only for births within marriage (Office for National Statistics 2002) successive attempts to change this eventually succeeded and from April 2012, parity, defined as the total number of previous live and still births was recorded for all births registered in England and Wales.

Multiple births

Multiple births accounted for nearly a quarter of infant deaths of babies born in 2007 weighing under 1500 g at birth and well over a tenth of all infant deaths among babies born in that year, as Table

Fig. 1.19 Infant mortality by mother's country of birth, England and Wales, 2007–9. (Data from Office for National Statistics, *Childhood Mortality Statistics*.)

1.13 shows. Figure 1.15 gives an indication of how the relationship between mortality rates for singleton and multiple births changes with birthweight within the category below 1500 g. Overall infant mortality rates are higher for multiple than for singleton births. Not surprisingly, mortality is highest among babies born in triplet and higher order births. This can be seen in Table 1.24, in which infant mortality rates for babies born in multiple births in the years 1975–2007 are compared with those for singletons. Mortality among twins and among triplet and higher order births fell markedly in the 1970s, then fluctuated around a similar level in the 1980s.

Despite year-to-year fluctuations because of the small numbers involved, there was a marked decrease from the early 1990s onwards. No data are available about the extent to which the increasing survival of triplet and higher order births is associated with morbidity in the survivors. These births create problems not only for the staff of neonatal units but for parents faced with the problems of caring for three or more babies of the same age. These have considerable implications for families and for the health and social services so the downturn in the triplet rate has welcome consequences (Botting et al. 1990).

Geographical variations and international comparisons in mortality

Variations from district to district in perinatal and infant mortality rates have always received considerable attention from the press and Parliament (House of Commons Social Services Committee 1988; National Audit Office Maternity Services 1990). Politicians have sometimes assumed that these variations simply reflect differences

in the quality of maternity care. As a result, they have tended to imply that districts and countries with the highest rates simply have to copy the practices of those with the lowest rates and the problem will be solved almost instantly. As a consequence of this, crude perinatal and infant mortality rates and their components have frequently featured over the years in government performance indicators and targets, both as proxy measures of the health of the population and as proxy measures of the quality of healthcare in an area. In recent years, they have been chosen to be two of the key outcome indicators for the NHS in England (Department of Health 2011). Closer inspection of these data shows that these interpretations are oversimplified and that the differences arise from a number of factors.

First, there is the question of which babies to register as births and deaths and which to categorise as miscarriages, which go unrecorded. Decisions about this are likely to reflect cultural, religious and social factors, which may vary from place to place.

Next, it is necessary to consider random variation. Neonatal and infant mortality rates for administrative districts within the UK, such as local authorities in England, are now based on such small numbers of events that what appear to be quite large differences from area to area, or from year to year within an area, are actually no larger than would be expected by chance, as Figure 1.20 shows. In the 1980s, OPCS published perinatal and infant mortality rates for NHS districts in England and Wales based on 3 years' aggregated data in addition to rates for the most recent year. The plethora of boundary changes in the 1990s made it difficult to go on aggregating data. Finally, the Office for National Statistics stopped putting data for NHS areas in the public domain and only NHS staff have access to them, although data for local authority areas are still published.

(Data from Office for National Statistics childhood mortality statistics, 2009, Table 10. Office for National Statistics, 2011)

**Fig. 1.20** Infant mortality rate by local authority, with 95% control limits for the overall rate based on numbers of live births, England, 2009. Data from the Office for National Statistics published by the National Centre for Health Outcomes Development.

The data shown in [Figure 1.20](#) are therefore based on data for local authorities for a single year ([Information Centre for Health and Social Care 2011c](#)). This shows the infant mortality rate for each local authority in England in 2009 plotted against the number of live births to residents in this year. The horizontal line is the rate for England. The curved lines are its 95% control limits for the relevant numbers of live births. It can be seen that in some of the smaller authorities the rates differed considerably from that for England, without going outside the 95% limits. In these instances, the difference between the authority's rate and that for England is no greater than would be expected by chance.

Random variation should also be taken into account when making comparisons between countries, especially when some of them have small populations. [Table 1.25](#) shows neonatal mortality rates for countries participating in the Europeristat project, together with 95% confidence intervals ([Buitendijk et al. 2003](#)). These show that even the differences between crude mortality rates are by no means as clear-cut as is commonly assumed and underline the extent to which some countries' rates are based on small numbers of events.

Returning to England and Wales, a special analysis for the years 1983–5 found that the districts whose mortality rates fell below the

Ireland provided data on early neonatal death.
(Data from [Mohangoo et al. \(2009\)](#).)

lower 95% confidence limit tended to be those with a high proportion of fathers in professional occupations and a low proportion of mothers born in the 'new Commonwealth' or Pakistan ([Botting and Macfarlane 1990](#)). Most analyses showed a high correlation between perinatal mortality rates and the proportion of low-weight births.

This study showed that, when mortality was analysed within birth-weight groups, different districts had high and low rates.

These analyses lent support to earlier proposals that birthweight-specific mortality rates were a better proxy measure of the quality of services than crude mortality rates. These had also proposed that

multiple births and deaths attributed to congenital anomalies should be excluded. Now that, as a result of both decline in natural incidence and the introduction of screening programmes, mortality attributed to central nervous system anomalies has declined to a much lower level, its inclusion is no longer such a critical factor. In any case, it would be more helpful to use birthweight-specific mortality rates as health service indicators or outcome indicators than to continue the present practice of using crude rates, as successive governments persist in doing. It is also a principle to consider when looking at trends over time and differences between countries.

The extent to which differences in the incidence and reporting of low birthweight can affect international comparisons of infant mortality rates is illustrated in [Figure 1.21](#), which is based on data from the Europeristat project referred to earlier. It shows the contribution of preterm and very preterm births to neonatal deaths in 2004 in the participating countries which had data about gestational age ([Europeristat 2008](#)). Because of these differences, the World Health Organization has recommended that babies with gestational age below 22 weeks and birthweight below 500 g should be excluded from comparisons between countries ([World Health Organization 1992](#)). Even when a common cut-off is applied, however, birthweight and gestational age-specific mortality vary markedly between countries ([Europeristat 2008](#)).

Classification of clinical causes of death

In publications based on death registration, information about causes of death is usually classified to a single underlying cause using the *International Classification of Diseases*, which is revised approximately every 10 years by the World Health Organization. Since the mid-1990s, the 10th revision (ICD-10) has been widely used for most purposes ([World Health Organization 1992](#)). The exception is stillbirth and death registration data. Use of ICD-10 for this purpose started in 2000 in Scotland and in 2001 in England, Wales and Northern Ireland. The ICD is designed primarily for use in circumstances in which only limited amounts of clinical information, such as that given on death certificates, is available.

In the perinatal field, other classifications have been developed for use by people with access to the more detailed clinical information found in case notes and pathologists' reports. Perhaps the best known is the classification first developed in Aberdeen in the 1940s by Sir Dugald Baird ([Baird and Wyper 1941](#)). This was revised in the early 1980s for use in stillbirth and neonatal mortality surveys in Scotland and the northern region of England, and has separate classifications for conditions in mothers ([Cole et al. 1986](#)) and babies ([Hey et al. 1986](#)).

A further classification, designed by a pathologist, Jonathan Wigglesworth, is based on externally observable features, supplemented by information from the clinical history ([Wigglesworth 1980](#)). A modified version, produced for the International Collaborative Effort on Birthweight, Plurality, Perinatal and Infant Mortality, was designed for use by people who are further removed from the clinical details, and is therefore based on the underlying cause of death coded using the ICD ([Cole et al. 1989](#)). It also extended the classification to cover conditions associated with death in the post-neonatal period. OPCS used this as a basis for a classification it developed for use on the new form of stillbirth and neonatal death certificate introduced in 1986 ([Alberman et al. 1994](#)). These certificates have separate spaces to list conditions in the mother and the baby and other factors relating to the death. The system was further developed for classifying stillbirths ([Alberman et al. 1997](#)).

Since then, the classification has been used routinely by the Office for National Statistics in its published tabulations of cause of death. It was revised for use with ICD-10 and extended to postneonatal mortality rates ([Dattani and Rowan 2002](#)). It is illustrated in [Table 1.26](#), which shows stillbirth and infant mortality rates for 2009. As described in [Chapter 2](#), there have subsequently been developments in the way the Wigglesworth classification is used to classify information from clinical case notes.

Confidential enquiries

As a result of public concern about levels of perinatal and infant mortality in the late 1970s, many special regional and local surveys and enquiries were set up. These varied in their format. Some were largely restricted to reviews of case notes, whereas others involved interviews with bereaved parents. Some took the form of confidential enquiries, based on the model of the Confidential Enquiries into Maternal Deaths. Some of these initiatives were for a single year or a limited period ([Enkin and Chalmers 1980](#)). Others, notably those in Scotland and in the former Northern and South East Thames regions of England, had been in existence for some years.

The rise in infant mortality in England and Wales in 1986 prompted a further enquiry into perinatal, neonatal and infant mortality by the backbench [House of Commons Social Services Committee \(1988\)](#), as it was then called. This recommended 'a targeted programme to reduce perinatal and infant mortality rates, particularly in poorer families where rates are still unnecessarily high'. In addition, it said: 'We recommend that all regions introduce a regular system of confidential inquiries into all unexplained infant deaths and report to the Department of Health on a regular basis. We also recommend that regions and the Department of Health set up a system for monitoring the results of such inquiries and making the lessons learned available to all health districts.'

In its reply, published in 1989, the government announced that it would be setting up a Confidential Enquiry into Stillbirths and Infant Deaths, and the Chief Medical Officer was setting up a working group to consider what form it might take ([Department of Health 1989](#)). Secondly, it acknowledged that many regions already conducted epidemiological surveys of stillbirths and neonatal deaths and it had asked the NHS Management Executive to ensure that all regions were doing them by April 1991. Instead of a targeted programme to reduce infant mortality, it stated that: 'Targets need to be set to improve performance' ([Department of Health 1989](#)). The Chief Medical Officer's working group reported in 1990 ([Department of Health 1990](#)). It recommended a national enquiry, with a regional and district reporting structure, into subsets of individual late fetal losses, stillbirths and infant deaths.

The Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) was set up in 1992, with a budget of over £2 million per year for England ([Horam 1997](#)), Wales and Northern Ireland to conduct its own enquiries on the same lines, and the data for all three countries are combined. Scotland has been conducting its own enquiries over a much longer period. As the name suggests, the enquiry's brief was to collect information on all late fetal losses at 20–23 weeks of gestation and all stillbirths and deaths in the first year of life, and to try to establish ways in which these deaths might be prevented. It was also to establish panels in each former NHS region to perform enquiries into a designated subset of the deaths.

One of its first priorities was 'sudden unexpected deaths in infancy', a category which went wider than the 'sudden infant death syndrome'. These were the focus of its 1994 report ([Confidential Enquiry into Stillbirths and Deaths in Infancy, 1996](#)) and of two papers in the *British Medical Journal* on smoking and sleeping position ([Blair et al. 1996a, 1996b](#)). These distracted attention from the

Fig. 1.21 The contribution of preterm births to neonatal mortality in EU member states participating in the Europeristat project. (Data from Europeristat 2008.)

fuller data published in the CESDI report, which showed that a high proportion of the babies who died were in very deprived circumstances (Confidential Enquiry into Stillbirths and Deaths in Infancy 1996; Logan et al. 1996; Macfarlane 1996a).

CESDI's other early priority was intrapartum-related deaths of normally formed mature babies. These were the subject of confidential enquiries from 1993 to 1995, the initial results of which

were published in CESDI's report for 1995 (Confidential Enquiry into Stillbirths and Deaths in Infancy 1996, 1997). In 1996 and 1997 the deaths of a random sample of immature babies were the subject of confidential enquiries (Confidential Enquiry into Stillbirths and Deaths in Infancy 1996, 1997). After that, enquiries have focused on large babies, babies born at 27 or 28 weeks of pregnancy, the outcome of diabetic pregnancies (Macintosh et al.

2006) and obesity in pregnancy (Fitzsimons and Modder 2010) and annual reports on perinatal mortality in England, Wales, Northern Ireland, the Channel Isles and the Isle of Man.

After being taken over by the National Institute for Health and Clinical Excellence, which reviewed all the four confidential enquiries, CESDI was merged with the Confidential Enquiry into Maternal Deaths and given a much wider remit as the Confidential Enquiry into Maternal and Child Health. The Enquiry transferred to the National Patient Safety Agency in April 2004 and the organisation subsequently changed its name to the Centre for Maternal and Child Enquiries (CMACE).

In 2010, the National Patient Safety Agency ran a competitive tendering exercise for confidential enquiries, redesignated as the Clinical Outcome Review Programme. The work previously undertaken by CMACE was split into two programmes of work: (1) maternal and newborn; and (2) child health. The contract for the maternal and newborn programme was awarded to a consortium led by the National Perinatal Epidemiology Unit and that for the child health programme was awarded to the Royal College of Paediatrics and Child Health.

In late March 2011 the National Patient Safety Agency decided to discontinue the procurement process for the maternal and newborn confidential enquiry pending a review to be completed by July 2011. The National Patient Safety Agency took steps to try to ensure that data collection continued while this was under. Responsibility passed to the Healthcare Quality Improvement Partnership (HQIP). The review report, published in July 2011, recommended that the programme be re-tendered and that a contractor should be appointed by April 1 2012. This gap is likely to have had some impact on the quality and completeness of the data collected. The award of the contract for the child health programme was unaffected by this.

Morbidity in childhood in relation to circumstances at birth

Although trends in mortality since the mid-1980s are somewhat uncertain, it is clear that over the preceding 20 years there was a dramatic decline in neonatal mortality, particularly among very small and immature babies. This raised the question of whether this fall in mortality was associated with an increase, a decrease or no change in the rate of morbidity among the survivors. Although there are a large number of follow-up studies, it has been difficult to answer this question. This is because information about long-term morbidity has not been collected in a standardised and comparable way, either in the countries of the UK or in most other countries.

There are few routine sources of information on morbidity available and most of these do not routinely link health in childhood to circumstances at birth, although the move towards greater use of record linkage may change this in the future. Because of this gap, data about morbidity in children who were born with low birthweight or preterm or who needed neonatal intensive care for other reasons are available mostly from studies of cohorts of babies cared for in individual hospitals or born to residents in geographically defined populations. Comparisons between these studies and over time is difficult, for a number of reasons, which are described in detail in Chapter 3.

The increasing demand for neonatal care

The increase since the 1960s in the proportion of babies who are born alive and who survive the first few days of life has led to a

corresponding increase in the numbers requiring care over and above the normal level of postnatal care given by mothers, with the support of midwives, health visitors, general practitioners and paediatric staff. The likelihood that a baby will need specialist neonatal care is highest among those with the lowest birthweight, and the proportion of babies of low or very low birthweight who survive birth has increased more quickly than the total numbers of live births. The current and planned future organisation of neonatal care and recommendations for data collection in the UK are described in Chapter 2, along with the history of neonatal care. The chapter ends with a description of the data collected routinely in the UK and what they do and do not tell us about trends in the care provided.

Trends in resources for neonatal care

Nationally available data about the NHS include numbers of cots in neonatal units and their use, numbers of paediatric medical staff and numbers of midwifery and nursing staff working in maternity and neonatal units. So far there is little information about the resources needed from health and social services and families once babies leave neonatal units, although these cannot be assumed to be negligible (Mugford 1990; Petrou and Mugford 2000).

Cots for neonatal care

Cots for neonatal care are funded differently depending on the type of care that is expected to be provided: the more intensive the nursing and the more equipment required, the greater the cost of providing the care. As techniques for care change continually, the definitions of levels of care, set out in Chapter 2, need to change in response, so the relevant professional bodies update these definitions from time to time. Until the late 1990s data collected routinely at hospital level counted staffed available cots for care of babies and included relatively little additional evidence about the type of cot or level of care provided.

Data about neonatal cots in England up to 1986 were derived from the SH3 Hospital Return. Numbers of available cots were based on a daily count of staffed available cots in each neonatal unit or special care baby unit (SCBU). Confusion can arise because the numbers of cots counted on the SH3 return were commonly referred to as 'special care cots' and levels of care within the neonatal units were not differentiated. As a result, the total number of cots included those designated for intensive care. The *Steering Group on Health Services Information* (1985) drew on the reports of the professional bodies mentioned above when compiling the definitions of special and intensive care used in the definition of cots for hospital statistics to be collected from 1987 onwards. Such designation is at best artificial, as it is likely that care considered to be intensive often takes place other than in the intensive care area within a special care nursery.

Data from the SH3 return and its counterparts showed that there was a fall in the absolute numbers of cots in SCBUs in each of the four countries of the UK in the early 1980s. These data, reproduced in *Birth Counts: Statistics of Pregnancy and Childbirth* (Macfarlane et al. 2000), also show decreasing rates of admission and longer lengths of stay for the babies who were admitted. With increasing concern in the 1970s and 1980s about the separation of babies from their mothers, policies of routine admission to special care for many babies changed. The admission rate fell from a high point of about 20% of births in England in the mid-1970s to just over 10% in 1987.

The basis for data collection changed in 1988, and in England the number and use of cots were from that time measured in two different routine systems. Numbers of hospital cots were recorded

in the KP70 hospital data system, and the use of cots was derived from the Hospital Episode System, both of which derived data from local health information systems and were administered centrally by the Department of Health. The numbers of cots for neonatal care appear to have continued to decline until 1990, with a levelling of the numbers and rates per 1000 births after that. Since 1996–7, the numbers of cots for intensive neonatal care have been shown separately.

Since 1988 it is no longer the number of admissions but rather the number of ‘finished consultant episodes’ (FCEs) that is counted. Any baby who is admitted for neonatal care but receives care from different consultants during one admission will be described as receiving more than one FCE during that admission. This can happen if surgery or specialist diagnostic skills are required. Not surprisingly, therefore, numbers of FCEs for babies admitted aged under 28 days and excluding healthy newborns, for 1989–90 until 1995–6, were much higher than the previous numbers of admissions to neonatal units.

Although this analysis of FCEs is not available for subsequent years, the Department of Health published analyses of occupancy,

the percentage of days an available cot is occupied, which show that, although there was a slight increase in the available cots per 1000 live births in the subsequent period, the occupancy was constant at about 70%, suggesting that an increasing number of intensive care cot days was being provided.

Since 1996–7, the KH03 form has listed numbers of intensive care cots in England. Data from that source for the financial years 2000–1 onwards, listed in Table 1.27, show that, although the numbers of cots provided have risen, they have scarcely kept pace with the rising birth rate and that occupancy rates have increased. In contrast, in Wales, where a broader definition of special care beds is used, their numbers have not risen and there are no clear trends in occupancy or length of stay.

Staff for neonatal care

The medical specialty of paediatrics has grown considerably, both in absolute numbers of ‘whole-time equivalent’ staff and in relation to the numbers of births, as Table 1.28 shows. All staff have been combined, because of changes in categorisation of staff in training.

*Whole-time equivalent.

†Rate per 1000 live births.

‡Figures for Northern Ireland for 1997 onwards are taken from the trust and board human resource management systems. They exclude all agency and bank staff. Bank staff maintain service delivery by covering staff shortfalls and fluctuating workloads. As a consequence their input to the service is difficult to measure. Owing to coding difficulties within the system, it is impossible to identify paediatric neurology staff working within paediatrics. Despite the fact that the attached figures are shown by paediatric departments, it is most probable that all medical staff working within paediatrics are not captured in these figures.

§England 2002 onwards does not include paediatric neurology.

¶Change in collection in 2001 in Scotland.

(Data from NHS Information centre, Workforce statistics.)

Data about the division of work between neonatology and other paediatric work are not routinely collected and so it is only possible to comment on the numbers in the specialty of paediatrics as a whole. Data are collected differently from each country's health administration and are not always available on the same basis. Northern Ireland data included community paediatricians and paediatric surgeons in the total figures for paediatrics and paediatric neurology and therefore the totals are not strictly comparable with those from the other countries. Publication of data by specialty appears to have stopped. In England, data about staff in paediatric neurology were not shown separately from 2002 onwards and in Scotland the introduction of a new data collection system in 2001 led to a discontinuity in counting.

The staff numbers are expressed as whole-time equivalents, with each member of staff being counted as the proportion of the full contract hours worked. This avoids the problem of how to count parttime staff, but trends over time can be misleading when nationally agreed hours of work change. It is important to note that changes in the contractual hours of doctors since the 1990s will have reduced the total medical time represented by the whole-time equivalent number of staff.

National data about midwives and nurses can be analysed to indicate how many of them work in maternity areas. These do not show neonatal care separately, although a new system for collecting workforce statistics in England, introduced in 2010, will make this distinction ([Information Centre for Health and Social Care 2010](#)). In many maternity units a certain amount of neonatal special care, such as phototherapy, is given in postnatal wards. Because of this blurring of the boundary between different levels of care, it is important to continue to look at the total numbers of maternity unit staff available per birth, as well as the numbers of neonatal unit staff.

The total numbers of qualified hospital nurses and midwives working in the maternity area who were in post on 30 September in

each of the years 1998–2010 in England are presented in [Table 1.29](#). Data are shown only for England, as the other countries of the UK do not provide data in this form. In 1980, changes were made in the nationally agreed hours of work for nursing and midwifery staff in the UK. The change in weekly working hours from 40 to 37.5 had the effect of increasing the whole-time equivalents of part-time staff artificially by 6.7% with no actual increase in available staff. Data for the 1980s and 1990s, showed that the numbers of whole-time equivalent midwives and nurses did not increase, and the rate per 1000 live births fell over the period ([Macfarlane et al. 2000](#)). This trend is associated with a change in training for nurses under Project 2000. Before 1989 student nurses and midwives were counted as part of the NHS workforce, but students then became supernumerary and were not recorded in staff numbers, but more recently they have been counted as support staff.

From 2003 onwards, there were substantial increases in whole-time equivalent numbers of nurses and midwives in England, but, as [Table 1.29](#) shows, they did not keep pace with the increases in numbers of births. Over this period, there were other changes, with the introduction of consultant nurses and midwives and of modern matrons. [Table 1.30](#) shows that there were also changes in the numbers and designation of support staff in the maternity areas. Most notable was the increase in numbers of healthcare assistants, defined as staff who are trained or under training in the various competencies related to their jobs and who work in specific clinical areas or are part of specific clinical teams. In practice, the work they do varies widely, so it is difficult to quantify their contribution ([Sandall et al. 2007](#)).

The need for better data

Although the existing data give a broad picture of the epidemiological context of neonatal care, there are many gaps and

inconsistencies. There has been considerable activity in data definition and, more recently, in the development of neonatal systems, but no corresponding expansion in published data. In addition, to interpret these, better data are needed about all births. Here again there are positive developments in plans for data collection and

record linkage, but at the time of writing the major concern in the UK is the lack of resources, including for data collection and monitoring services, which means that even the existing data systems are being cut and staff expertise is being lost.

Conclusions	69

Asphyxia, prematurity, sepsis and malformations remain the major causes of mortality and morbidity identifiable at birth and result in around 4 million deaths each year worldwide. Neonatal intensive care (NIC) has made huge inroads into reducing the mortality and to some extent the morbidity associated with the first three causes, which has resulted in improving survival at increasingly low gestations. Such care, however, is increasingly under pressure as the result of budgetary and skill base constraints.

Within many health systems it is not feasible to provide such expertise and facilities in every setting in which babies are born. Most health services in the developed world have developed increasingly specialised models of neonatal services, concentrating skills and facilities for providing intensive care, ensuring high levels of basic skills close to every birth and dedicated transport facilities to ensure babies receive optimal care in the correct setting to maintain improving outcomes. Such a system is high cost and low throughput compared with many health services, including maternity care.

Concentration is not without problems and increasingly centralised care means much larger delivery units with inherent problems for the obstetric and midwifery teams and pregnant women, and is in conflict with the desire of many groups to provide birth in more 'natural' settings for women at low risk of neonatal complications. These tensions lead to much controversy, which is fuelled by the lack of reliable data with which to evaluate safety in various settings.

In this chapter, therefore, organisation of care will be discussed alongside systems for ensuring that care is safe and effective in different settings and monitored at service, unit and patient level.

Organisation of care

NIC services have developed differently in different health systems, to some extent dependent upon the proximity of the children's and maternity services. In some health systems NIC is located within a children's hospital, which has advantage for paediatric specialist care but places the postpartum mother at a disadvantage and all children have to be transferred in for specialist care. In other systems NIC has developed alongside maternity services, often in isolation from supporting paediatric services. The degree of centralisation of services has also been driven by external factors, either by market forces in privately funded systems or by population distribution. Many health systems mix these structures according to local

geography. The relationship between organisational structures and outcome is highly contentious and not easily amenable to study (see below).

Pressures of health economics have driven most services to concentrate intensive care services in fewer expert centres and to review the structure and function of other neonatal services (which care for the majority of babies) in terms of their effectiveness at providing a highly expert resuscitation service or limited intensive care. One example of this is the development of highly centralised NIC in Western Australia, with a land mass 20 times the size of England and a population of 2.2 million compared with 60 million, respectively. There are relatively few large population centres; the whole state is served by two intensive care centres (one in a children's hospital) and a highly developed antenatal and neonatal retrieval service. This contrasts with the 178 neonatal units currently providing intensive care for extremely preterm babies in the UK (Watkinson and Davis 2009). Many European countries have developed NIC within children's hospitals, and thus all babies needing care are transferred in, often from very much smaller and less expert clinics. Slowly this model is being replaced by a centralised system where expertise can be concentrated in fewer and better-resourced maternity/neonatal centres.

Several classifications or categorisations of neonatal units have been used. Most use the concept that a three-tier service is most efficient: the least intensive category of unit provides only short-term stabilisation prior to transfer, the most intensive carries out a full range of intensive care activity, and the intermediate tier provides varying degrees of postnatal support depending on local resources. Evidence is evolving that care in the highest tier centres produces higher survival and less morbidity; the difficulty is how to ensure babies are delivered in an appropriate setting. Current UK definitions are shown in Table 2.1.

Such organisation can only function if units work together as a de facto clinical network and if the health commissioners work to ensure that each network has the capacity and resources to provide for the predicted demand. Parents of babies also need to understand the concept, and the fact that their baby will be moved, should intensive care become necessary, which is against current trends for

care to be delivered in the hospital or setting of choice. Such a working pattern has major potential advantages in terms of high-throughput neonatal intensive care units (NICUs) for the maintenance of clinical skills, high occupancy for intensive care cots permitting efficient use of resources and ability to staff the high-intensity areas.

Within the UK, intensive care resources for adults and for children have been incorporated into managed clinical networks. Services are planned based on a geographic population with different ranges of facilities at each centre. The key issue in the success of these services is the central management of resources across several otherwise independent health service units (trusts). The argument for centralisation of paediatric intensive care has been well made (Ratcliffe 1998) and improved early care, triage and outcome can be anticipated through the underpinning of the network with a strong educational and training base. Despite these structures it remains important in any health system that children access the appropriate level of care (Maybloom et al. 2002).

Overall the demand for NIC has risen (Ch. 1). In parallel, the UK has seen increasing public demand for transparency in the delivery of healthcare, in the wake of several high-profile government reports, and there is a drive to ensure that care is provided by professionals whose expertise is appropriate to the clinical situation. Recent changes in law are leading a reduction in the traditionally overlong working hours for doctors and there is currently a paucity of nursing and specialist doctors to provide specialist neonatal care, fuelling calls for further centralisation.

Current provision of neonatal care in the UK

Women and their families expect that pregnancy, delivery and postnatal care will be delivered in one local centre as close as possible to the family home, and this perception is encouraged by healthcare managers within the National Health Service (NHS) hierarchy. Problems arise when difficulties with either the woman or the fetus develop that cannot be managed by local services. At present further management is dictated by the availability of obstetric and neonatal resources at the referral centre. Central to the planning of care is the

Table 2.1 Types of neonatal services within a network

LEVEL	DESCRIPTION
Level 1	Special care units (SCUs) provide special care for their own local population. Depending on arrangements within their neonatal network, they may also provide some high-dependency services. In addition, SCUs provide a stabilisation facility for babies who need to be transferred to a neonatal intensive care unit (NICU) for intensive or high-dependency care, and they also receive transfers from other network units for continuing special care
Level 2	Local neonatal units (LNUs) provide neonatal care for their own catchment population, except for the sickest babies. They provide all categories of neonatal care, but they transfer babies who require complex or longer term intensive care to a NICU, as they are not staffed to provide longer term intensive care. The majority of babies over 27 weeks of gestation will usually receive their full care, including short periods of intensive care, within their LNU. Some networks have agreed variations on this policy, owing to local requirements. Some LNUs provide high-dependency care and short periods of intensive care for their network population. LNUs may receive transfers from other neonatal services in the network, if these fall within their agreed work pattern
Level 3	Neonatal intensive care units (NICUs) are sited alongside specialist obstetric and fetomaternal medicine services, and provide the whole range of medical neonatal care for their local population, along with additional care for babies and their families referred from the neonatal network. Many NICUs in England are co-located with neonatal surgery services and other specialised services. Medical staff in a NICU should have no clinical responsibilities outside the neonatal and maternity service
Reproduced from Report of the Neonatal Intensive Care Services Review (2009). A Toolkit for Quality Neonatal Services. London, Department of Health.	

need to forewarn parents of the likely arrangements if problems develop, so that families are not suddenly faced with the prospect of their care being transferred to another centre, often at some distance, without warning.

In the late 1990s, 246 units provided neonatal care across the UK, 76% of which provided intensive care. This dispersed model had developed as a result of market forces, there being few attempts to centralise care at the time. Since then several national initiatives have effectively centralised care for the extremely preterm baby, using the establishment of managed clinical networks for neonatal care to bring a measure of coordination of care and resources (Marlow and Gill 2007). Currently, neonatal care in England is organised as 22 networks, each centred on one or more lead perinatal centres (usually a university hospital) based on 15 000–25 000 births per annum. The structure of a model neonatal network is shown in Figure 2.1. Management of the network is organised independently of any of the contributing hospitals, in order that resources can be managed effectively and independently of local ambitions. In all networks, care for babies at 26 weeks of gestation or less is centralised, regardless of delivery site, and all have developed a measure of common guidelines and practice.

More recently the NHS has published its framework for NIC (www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_107845). This comprehensive document identifies important regional organisation to support NIC and includes a set of quality standards against which neonatal practice can be audited.

With the introduction of the managed clinical network it should be possible to map out a plan for most eventualities, so that a pregnant woman understands the management plan for the anticipated normal pregnancy, what is to happen if a fetal anomaly is discovered, what will happen if very preterm delivery seems likely and what care arrangements are to be made if there is an unanticipated need for NIC. Despite the often-quoted maxim that pregnant women do not wish to travel for their care, all the evidence points to the woman willingly allowing transfer of care if it is clearly in her baby's best interests.

Fig. 2.1 Structure of a neonatal network in England. CPD, continuing professional development. (Redrawn from Report of the Neonatal Intensive Care Services Review (2009).)

Classification of neonatal care in the UK

One difficulty in determining the size of the workforce needed to staff a neonatal service is the range of activity and case mix of different services. It is thus helpful to define a range of categories of care which may allow the planning of resources.

Within any type of neonatal unit, care for an individual baby can be classified by the level of clinical dependency, which should provide a measure of the resources needed to look after that baby. The definitions of these categories of care will differ between health systems. Within the UK there are several contenders, some of which have been developed using formal studies (Williams et al. 1993), whereas the nationally recommended categories (British Association of Perinatal Medicine 2001, 2010; Report of the Neonatal Intensive Care Services Review 2009) have been developed by professional consensus; we presently recommend that inpatient neonatal care is divided into three categories (Box 2.1).

These categories of care are of value in establishing what level of nurse staffing is necessary to provide cot-side care. Generally, minimum levels specify one nurse to one cot for intensive care, one nurse to two cots for high-dependency cots and one nurse to four cots for special-care cots, although achieving one-to-one nursing is a challenge in the current economic climate with the available workforce skills, and remains aspirational. These minimal requirements do not include managerial and other specialist roles (advanced practice, family care, practice development), which have evolved within the nursing sphere, but require extra resources.

These levels of neonatal care are more tightly defined nationally via the national Neonatal Critical Care Minimum Dataset (<http://www.isb.nhs.uk/documents/dscn/dscn2006/142006.pdf>) to ensure that there is consistency in definition across the country. The number of intensive care days needed for a particular population will vary depending primarily on the number of low-gestational-age babies cared for, as they utilise the majority of resources. This in

Box 2.1 Categories of neonatal care

- Special care (SC) is that provided for all other babies who could not reasonably be looked after at home by their mother. Babies receiving special care may need to have their breathing and heart rate monitored, be fed through a tube, supplied with extra oxygen or treated for jaundice; this category also includes babies who are recovering from more specialist treatment before they can be discharged. Special care which occurs alongside the mother is often called 'transitional care' but takes place outside a neonatal unit, in a ward setting
- High-dependency care (HDC) takes place in a neonatal unit and involves care for babies who need continuous monitoring, for example those who weigh less than 1000 g (2 lb 3 oz), or are receiving help with their breathing via continuous positive airway pressure or intravenous feeding, but who do not fulfil any of the requirements for intensive care
- Intensive care (IC) is care provided for babies with the most complex problems who require constant supervision and monitoring and, usually, mechanical ventilation. Because of the possibility of acute deterioration, a doctor must always be available. Extremely immature infants all require intensive care and monitoring over the first weeks, but the range of intensive care work extends throughout the whole gestation period

(Reproduced from Report of the Neonatal Intensive Care Services Review (2009). A Toolkit for Quality Neonatal Services. Department of Health, London.)

turn is dependent upon the social and environmental mix of the population: within the regions of the south-east of the UK, which includes inner city and rural districts, the cot requirement in each region varied between 1.0 and 1.9 intensive care cots per 1000 births, estimated at the recommended 70% occupancy, using older definitions.

To these categories of care, which are dependency based, many hospitals have an intermediate category between the neonatal unit and routine postnatal ward, so-called transitional care. This is primarily aimed at nursing babies who still need 'special care' (for example, gavage feeding) but can be managed in an area alongside their mother and supporting the mother while she provides the majority of care (Ch. 21). In different hospitals this is developed and organised differently and there are no formal definitions to facilitate comparisons. Transitional care has an important effect on neonatal unit activity in that some special care activity is transferred out to a ward staffed primarily by midwives and thus is not always counted in terms of service activity. This may free up staff to assist with the more intensive activity in the neonatal unit, changing the skill mix requirements. In addition, it becomes a local responsibility to determine staffing levels for transitional care and to ensure that adequate support for mothers is available. Despite these difficulties it is a cost-effective and desirable care strategy, encouraging maternal-infant interaction more effectively than remote management on a NICU.

Staffing

Having defined the types of neonatal services and categories of care, the staffing requirements for a neonatal service can be established.

Medical staffing is dependent upon the degree of cross-covering required to run the service and this is in turn dependent on the intensity of care that can effectively be offered:

- For special care units, it is envisaged that no intensive care will take place. Staff will be available in the hospital to attend infrequent emergencies and this cover will be provided as part of an acute paediatric service.
- For local neonatal units, continuous bedside medical support is required, either by a trainee (senior house officer (SHO) or resident) or by an advanced neonatal nurse practitioner (ANNP), while middle and consultant tier cover is provided as part of the adjacent acute paediatric service.
- For NIC services, dedicated specialist staff are required with two resident tiers (SHO/ANNP and registrar/consultant), with a supervising consultant available to provide continuity.

In 1996, 25% of units providing intensive care did not have a consultant with more than 50% time dedicated to neonatal care (Tucker et al. 1999). This appears to have somewhat improved by networking. This is clearly unsatisfactory given the huge strides in neonatal care over the past 30 years. As workforce directives reduce the working hours available for all staff, the grade and competency of staff providing first-call care must be examined carefully if we are to continue to provide high-quality care. In some units this is now contributed to by advanced nurse practitioners, who form an intermediate tier of carers outside the clinical practice nursing teams, because of their expertise and wider responsibilities.

Nurse staffing relates to dependency levels and generally is calculated from an estimated establishment for a particular cot number and configuration. Daily monitoring will confirm the adequacy of this. Nurse staffing is the largest part of the unit budget and thus most vulnerable: in 1996, 79% of units had a ratio of nursing

provision to that recommended of less than 1.0 (median 0.84; interquartile range 0.73–0.98), indicating significant underestablishment for the activity that was being carried out, despite taking conservative staffing levels as the norm (1:2 intensive care and 1:4 for all others) (Tucker et al. 1999). This wide variation in the adequacy of local resources to carry out neonatal care is reflected in the findings of other studies (Parmanum et al. 2000) and has provided the impetus for the current changes in service structure (see below). In a repeat census taken as part of the EPICure 2 study, 73% of units now met this conservative criterion, indicating improved nurse staffing over the 22% found in 1996.

In addition to medical and nursing staff, a range of other supporting skills is required, including allied health professionals (physiotherapy, occupational therapy, speech and language therapy) and other support staff (British Association of Perinatal Medicine 2010). As care for the newborn infant demands different skills from those required for nursing sick older children or adults, specific competencies have been defined for these groups (Report of the Neonatal Intensive Care Services Review 2009; British Association of Perinatal Medicine 2010).

Transfers

Any configuration of neonatal services within a region is dependent upon the availability of both cots and effective patient transport. Transfer of the pregnant woman or her infant is commonplace but within the current service the destination of any transfer cannot be determined with any certainty, as beds are often unavailable at the natural referral centre. Part of the drive to reconfigure services is to remove this lottery.

The relative merits of in utero and postnatal transfer for care require careful consideration. Studies comparing the results of each all have an inherent bias, as the need for intensive care or ventilation cannot be predicted before birth and postnatal transfer will generally be for ongoing ventilator care, although some babies may die before transfer can be effected. Thus a true study on unselected populations is almost impossible to achieve. Nonetheless, within well-centralised systems, with often independent transport services such as in the USA (Bowen 2002) and Australia (Rashid et al. 1999), a more consistent service can be achieved. Even within the UK there is evidence that babies are not placed at significant risk during a well-planned transfer (Leslie and Stephenson 1997, 2003). There are however data that suggest that mortality is increased when transfer is requested but unavailable (Bennett et al. 2002) and babies moved between tertiary centres unable to cope with peaks of demand have poorer outcomes (Parmanum et al. 2000). The key to effective transfer is the establishment of adequate capacity within a clinical network, to allow planned flows of referrals that can be discussed in early pregnancy with all pregnant women.

One study has evaluated the pattern of 'inappropriate transfers' as a measure of the adequacy of capacity in tertiary units (Parmanum et al. 2000). Inappropriate transfers were defined as those out of a perinatal centre. Over 3 months in 1999, 264 in utero transfers and 45 postnatal transfers were recorded in 37 such units. Rates of transfer in each region varied from 0.20 to 5.44 per 1000 live births. The risks and outcomes of these transfers were studied in 242 cases (Bennett et al. 2002). Of in utero transfers, only 61% delivered at the accepting hospital, 12% were moved to a third hospital following delayed delivery and 29% were returned to deliver at their referring hospital. One mother delivered during the journey and nine delivered within 1 hour of arrival. Transfer of mothers and their babies should be a planned process with defined levels of referral and, as far as possible, guaranteed capacity at the natural referral centres.

In utero transfers

It is important to distinguish the urgency with which mothers are referred for specialist care, usually because of impending prematurity, from more elective transfers for expert assessment of fetal malformation or growth restriction. There must be close liaison between both obstetric and the receiving neonatal team before any decision to move a woman is undertaken. The presence of vaginal bleeding, pre-eclampsia or labour and the obstetric history of the woman must be carefully weighed against the need for transfer. Where urgent transfer can be effected safely this must be the best mode of transfer, as both mother and baby will be cared for in the same centre, separation avoided and the baby will be exposed to minimised postnatal risk. However there is a chance of delivery during the journey and a risk of other unforeseen problems, and not infrequently women are moved before birth because of a risk of early delivery and do not deliver. Many services attempt to stratify risk by the use of fetal fibronectin (Bolt et al. 2009) or Actim Partus (Balic et al. 2008) screening, as adjuncts to the diagnosis of preterm labour, in an attempt to avoid unnecessary transfer.

Postnatal transfers

In most areas of the UK, postnatal transfer services initially developed on an ad hoc basis. There are now formalised transport teams in most networks and competencies for staff have been identified (Ch. 13.2). Quality standards for neonatal transfers have been published (Report of the Neonatal Intensive Care Services Review 2009). In the past, such transfers were deemed 'flying squads', where a rapid emergency response team travelled rapidly to support the local team in early-care scenarios. With improvements in care and expertise at local hospitals it should be possible to effect elective transfers at a time that is clinically appropriate for the baby, although robust arrangements need to be put in place for dealing with emergencies arising in units without on-site specialist neonatal staff. No network transport service in the UK currently provides support to standalone midwifery-led units or to home births, where midwives are reliant on calling for help via the standard emergency ambulance service using 999. A centralised service has been shown to be effective in reducing waiting times and quality markers (Kempley et al. 2007).

Relationship of organisational factors to outcome

Given the stress placed above on the structure to support neonatal care, one would anticipate that care organised according to such principles clearly leads to better outcomes. Within the UK system this is far from clear. Several attempts to investigate this relationship have been undertaken. The relationship between organisational issues and mortality is the easiest to undertake but, given the decrease in mortality over the past 10 years, death is a relatively rare event and thus small differences in mortality are more difficult to demonstrate. Furthermore large tertiary units treat a different range of babies from those managed in local services and tend to be overcrowded, with high occupancy rates, and are more likely to be understaffed. Smaller units may also transfer out sick babies soon after birth and the mortality will be attributed to the receiving unit. The complexity of these issues makes it extremely difficult to draw conclusions from comparisons.

Studies of regional outcomes for mixed hospital groups have shown inconsistent effects. In the late 1980s mortality was higher for babies cared for in smaller units in the Trent region of the UK

than for babies cared for in larger units. This longitudinal study was reanalysed in the early 1990s following an NHS reorganisation and then demonstrated no difference in mortality by size of unit (Field and Draper 1999). This was ascribed to enhancements in neonatal provision at local hospitals, but clearly the relationship is more complex than that.

Scoring systems for neonatal illness provide one way of correcting for case mix, making adjustment for the illness severity measure when comparing outcomes. The use of such measures is established in paediatric and adult critical care services. In neonatal care the two most frequently used scoring systems are SNAP (Richardson et al. 1993) (plus SNAP-II and SNAPPE-II; Richardson et al. 2001) and CRIB (The International Neonatal Network 1993; Parry et al. 2003), although there are others. Care should be taken when using these measures, as they do not attempt to predict outcome for an individual but are scoring systems describing the clinical condition so that some adjustment between outcomes in a population can be made (Hope 1995; Marlow 2002). These scores require regular review and updating as techniques and interventions change. For example, a tertiary unit that uses delivery-room surfactant or early high-frequency oscillatory ventilation may appear to have low severity of illness scores (based on oxygenation) but similar mortality to other units because the gestational age of the babies cared for is lower. Hence the score itself may partly reflect the care given as much as the underlying characteristics of the baby, i.e. the score may itself be an outcome variable for perinatal care (Marlow 2002).

CRIB originally included data from worst base deficit and highest and lowest inspired oxygen concentrations over the first 12 hours, making it particularly sensitive to changes in early interventions. In contrast, CRIB-II uses temperature on admission and maximal base deficit over the first hour as the clinical variables, which, together with sex, gestational age and birthweight, provide the basis for the score (Fig. 2.2). Using this recently validated model with a high degree of predictive value for mortality (area under the receiver operating characteristic curve: 0.92) in an analysis of the data collected as part of the UK Neonatal Staffing Study, CRIB-II-adjusted mortality did not differ between large and small units in the UK (odds ratio (OR) 1.06; 95% confidence interval (CI) 0.70–1.60) (Tucker 2002).

Nonetheless, corrections for disease severity can provide useful information concerning the relative performance of neonatal services to facilitate the identification of areas for investigation and throw up intriguing questions when applied to cross-national (International Neonatal Network et al. 2000; Field et al. 2002) or national comparisons (Parry et al. 1998). For example, risk-adjusted mortality appears to be significantly higher in Scotland than in England or Australia (International Neonatal Network et al. 2000). The question is raised as to whether this relates to organisation of care, being highly centralised in Australia and devolved in the UK. Caution is required when interpreting these studies as the ethnic, social and demographic profiles of any population may account for more of the variance in outcomes than the perinatal services and the obvious difference, i.e. organisation, may be confounded by population differences. This is emphasised by a further comparison of outcome for babies born at <28 weeks of gestation or <1000 g birthweight between the Trent region of the UK and Denmark (Field et al. 2002). Births in this group were more prevalent in Trent and, despite a higher use of antenatal steroid, babies had higher CRIB scores, received more mechanical ventilation and were more likely to die than those in the Danish population.

The UK Neonatal Staffing Study randomly selected 54 of 186 units in the UK to study the relationship between throughput, consultant and nurse staffing and outcome as mortality, cerebral damage as detected by ultrasound and nosocomial infection (Tucker

The maximum (worst) score for birthweight and gestation is 15, which is obtained for a 22 week male infant of less than 501g birthweight

2002). Data from 13 334 babies were used. High-volume NICUs, treating the sickest babies, had the highest crude mortality but this difference disappeared when risk adjustment was made. However there were important findings relating the risk of dying to the staffing levels on the shift during which a baby was admitted. Babies admitted to a unit working at full capacity were 50% more likely to die than babies admitted to a unit working at 50% capacity (Fig. 2.3). The British Association of Perinatal Medicine (BAPM) has commented that this may be attributable to a number of factors, including inadequate staffing and change of case mix as workload increases. It is crucial that staffing levels and expertise are appropriate to the dependency of the babies.

In a further epidemiological study from the USA, there appeared to be an optimal relationship between neonatologist staffing and mortality (Goodman et al. 2002). The numbers of neonatologists and numbers of cots (expressed in quintiles from the distribution) were related to national statistics of neonatal deaths (in the first 28 days). On average there were 6.2 neonatologists, 33.7 intensive care cots and 17.7 high-dependency cots per 10 000 births. There was lower neonatal mortality where there were 4.8 neonatologists per 10 000 births than with 2.7/10 000 births (OR for death 0.93; 95% CI: 0.88–0.99) but increasing the number above this level did not result in further improvements. Furthermore the availability of neonatal cots was not related to mortality risk and the need for cots (as expressed by the number of babies with birthweight <1501 g) did not relate to cot availability. This must be placed in contrast to the calculated requirement of 10–19 intensive care cots per 10 000 UK births (see above).

In the current EPICure 2 study of births at 26 completed weeks of gestation or less in England during 2006, a time when the network model had become reasonably well established, it was apparent that survival for livebirths in this gestational group was higher overall in NICU services (59%) than in local neonatal units (51%) before (OR 1.51; 95% CI 1.16–1.98) and after adjustment for gestational age and birthweight (OR 1.60; 95% CI (1.17–2.19)). This advantage held when only those babies admitted were included, and this trend was also obvious among smaller and larger NICU services (OR survival livebirths 1.43; 95% CI 1.01–2.01), mainly because of higher survival at 23 and 24 weeks, respectively (EPICure 2 study group unpublished data).

The relationship between organisational factors and simple outcome measures is therefore far from clear but sides on larger services with higher staffing ratios have better outcomes in terms of survival. In the UK it is incumbent on each managed clinical network to ascertain and monitor the availability of cots and staff,

and access for its residents to the service when required, and to benchmark these services against other national data.

Philosophy of care and survival

Mortality at low gestations has improved over the past 20 years such that the great majority of babies born at 26 weeks of gestation or more now survive. Attitudes to the resuscitation and continuing care of babies born at lower gestational ages will thus have a profound effect on the rates of survival and thus confound comparisons of different services. These attitudes vary widely across the world. For example, at a time when care was unusual at 24 weeks in the Netherlands, in the UK we were demonstrating about 35% survival at 23–24 weeks and both national studies from Sweden (EXPRESS) (Fellman et al. 2009; EXPRESS Group 2010) and Australia and New Zealand (Donoghue and the ANZNN Executive 2009) report 50% survival for babies admitted for neonatal care (Fig. 2.4). However, the rates of serious neonatal and later morbidity remain very high in these survivors and cannot be ignored (Fellman et al. 2009) and wide variation in the approach to discontinuing care may distort survival further given that so many babies have elective discontinuation of care (Costeloe et al. 2000).

The extent of the differences brought about by extremes of practice was explored by Lorenz and colleagues (2001), who demonstrated marked differences in survival and prevalence of cerebral palsy in two studies with widely differing approaches to outcome (Ch. 3). Indeed, in the UK, regional centres with a proactive approach to the care of extremely low-gestational-age babies report survival at similar levels for babies born at 23 and 24 weeks to the highly centralised Swedish national data (Riley et al. 2008). Without a detailed study of the approach to care at these extremely low gestations the reasons for these differences cannot be explored and it would be incorrect to attribute them to quality of care.

Service evaluation

Clinical governance is the framework in which we as professionals ensure that our care is accountable to our patients and to our host institutions. There is a range of schemes for this and this section

will focus on those applicable to perinatal care under the following headings:

- the clinical governance philosophy
- clinical audit
- standards, guidelines and perinatal audit tools
- benchmarking and evidence-based care.

The clinical governance philosophy

Medical audit was promoted in 1989 by the UK government as a means of protecting the interests of patients in the then new health market, but audit and quality assurance were not new developments. It rapidly became clear that the performance of many services was based upon access and availability, or the personal style directed by consultants, rather than evidence-based practice. The concept was widened to clinical audit, involving multidisciplinary teams, and achieved some limited success. Neonatal and perinatal care provides a prime example of areas of truly multidisciplinary practice where collaboration must occur between doctors, nurses, midwives and other professional groups for a successful service to evolve.

Clinical audit gradually evolved into the wider concept of clinical governance in the late 1990s. The most widely used definition of clinical governance is 'a framework through which NHS organisations are accountable for continually improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish' (Scully and Donaldson 1998). Thus this is designed to introduce a systematic approach to the delivery of NHS care, in which there is corporate accountability for clinical quality and performance. The essential features of the process are not deniable:

- patient-centred care
- widely available information about the quality of care
- reduction in the variations of process, outcomes and access to care
- reduction in risks and hazards to patients
- widespread dissemination and adoption of good and research-based practice.

The key to the delivery of this process is reliable and comprehensive information about the service, something which has been sadly lacking in the NHS. Indeed, the reforms of the mid-1990s may be likened to an experiment without defined outcome measures (Maynard and Bloor 1996). The more recent reforms have increased reporting centrally and hence central control over services which have exacerbated the difficulties of running acute services with unpredictable workloads. The formation of managed clinical networks (see above) should help to resolve some of these issues.

The clinical audit process

Audit is defined as 'an evaluation (esp. by formal, systematic review) of the effectiveness of the management, working practices, and procedures of a company or other professional body' (Oxford English Dictionary 1989).

The key to the audit process is the setting of standards and the appraisal of the clinical service against those standards. This is often assembled into what is commonly called the audit cycle (Fig. 2.5). Standards may be set nationally, regionally or locally and may evaluate three major aspects of care:

1. the structure of the service
2. the process of care
3. the outcome of care or the result of clinical intervention.

Fig. 2.4 Comparison of survival for babies born at 22–25 weeks admitted for neonatal intensive care in three contemporary studies (note that the small number of 22-week survivors (*n*) accounts for variation in survival rate, and that current UK guidance does not support universal intervention at 23 weeks).

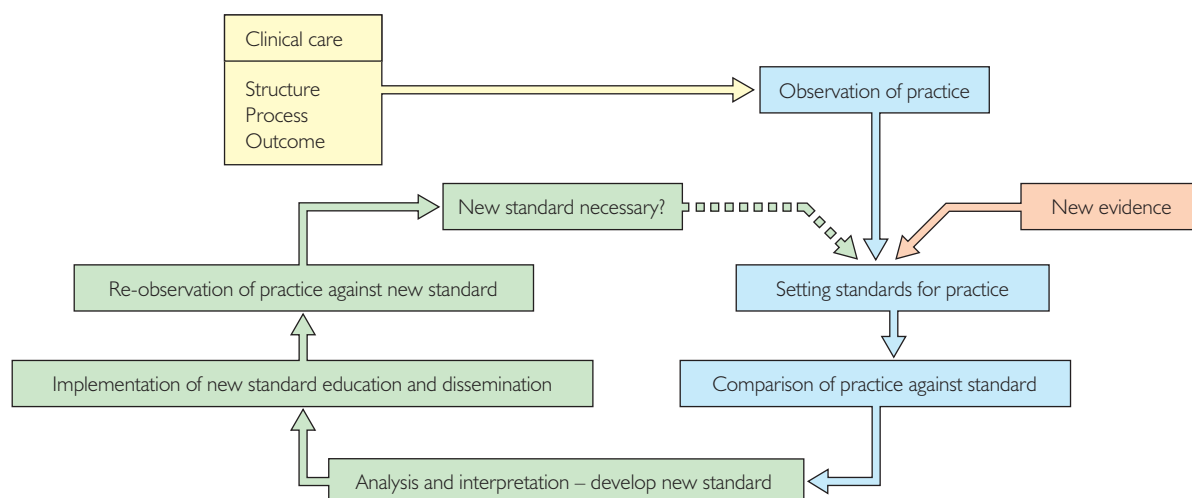

Fig. 2.5 The audit cycle. The cycle commences with the observation of practice and the integration of new evidence into the setting of standards and is completed when a new standard is re-evaluated to confirm the effectiveness of changes in clinical care.

Fig. 2.6 Appropriateness of nursing establishments in all UK neonatal units (actual/recommended numbers of nurses from published standards – lighter bars denote units with lower establishments than required). (Reproduced with permission from Tucker et al. (1999).)

The structure of care

This is concerned with the quantity and type of resources and how they are used, for example the number and experience of medical nursing or paramedical staff or the availability of cots. These data are relatively simple to collect and are usually accurate. Standards are produced nationally (see below) and these data can be powerful in the process of bidding for resources. For example, the shortage of neonatal nursing staff was emphasised in the UK Neonatal Staffing Study (Fig. 2.6), which is an example of a national audit of the structure of care.

Audit of structure by itself can only demonstrate potential areas where services may be inadequate and does not form a measure of quality of care until it is matched with patient-based information when it merges with the two other areas of audit. Structural deficiencies may provide one explanation for poor results found during process or outcome audit.

The process of care

The process of care may be considered in three ways:

1. the way patients progress through the system – examples would be admission and discharge procedures, the recording

of clinical data in the patient notes and the recording of communication with parents

2. the way particular resources are used – examples would be attendance at delivery by appropriate levels of staff, occupancy and case mix studies and the use of transitional care facilities
3. the way particular conditions are managed – examples here relate to particular admission criteria, diagnostic groups or to interventions. In this area evidence-based practice may be introduced into care via the development of guidelines.

An example of a nationally based audit of the care process is provided by the joint venture between the Royal College of Paediatrics and Child Health (RCPCH), BAPM and Royal College of Ophthalmologists. Standards for screening and treatment of retinopathy of prematurity were issued in 1995. Subsequently a nationwide education programme was undertaken followed by an audit of cases registered as requiring treatment and new guidelines were issued (Haines et al. 2005; Wilkinson et al. 2008).

The outcome of care

The outcome of care (or the result of interventions) provides the final arbiter of success for a service and includes important mortality and morbidity measures. Outcomes may relate to the child (occurrence of death, complications of treatment or longer term neurological development), the parent (satisfaction, breastfeeding rates) or the staff (recruitment, retention, levels of competency or ability to perform procedures).

Mortality rates are clearly defined (Table 2.2), widely available and many are collated nationally (Table 2.3 and Fig. 2.7) or regionally. Although these data offer the opportunity to set local targets and review local performance, extreme care should be exercised in their interpretation as they may be subject to random variation owing to small numbers and systematic variation in methodology of collection. Correction for illness severity has been recommended as a way of avoiding some of these problems (see above).

Choosing outcome measures for specific audit is fraught with difficulty. Outcomes need to be specific, measurable and relevant. For example, babies who receive pulmonary vasodilators to reverse pulmonary hypertension may be audited on their response to treatment, in terms of oxygenation over the period of use and immediately afterwards, but to use duration of ventilation or longer term outcomes (e.g. neurodevelopment) would be inappropriate as

Table 2.2 Perinatal definitions

Livebirth	Baby with signs of life observed after complete expulsion from the mother irrespective of the duration of the pregnancy (signs of life include breathing, heart beat, cord pulsation or voluntary movement)
Stillbirth (or late fetal death)	Fetal death prior to complete delivery of a baby born after the 24th week of pregnancy (168 days after the first day of the last menstrual period (LMP))
Abortion	A conceptus born without signs of life before the end of the 24th week of pregnancy (<168 days after LMP)
Birthweight	The first weight of a fetus or newborn baby obtained after birth (preferably within the first hour after birth)
Gestational age	The duration of gestation measured from the first day of the LMP expressed in completed weeks and days (note that gestational age is never rounded up and thus a baby born at 24 weeks and 6 days is usually considered to be of '24 weeks gestational age')
Preterm	Birth at less than 37 weeks of gestation (<259 days after LMP)
Term	From 37 to 42 completed weeks of gestation (259–293 days after LMP)
Postterm	More than 42 weeks (>293 days after LMP)
The neonatal period	The first 28 days after delivery
Lethal congenital malformation	Death primarily due to congenital malformation

Table 2.3 Total births and deaths for England and Wales 2006 by causes of stillbirth, neonatal and infant death

CAUSE GROUP	BIRTHS		DEATHS			ALL INFANT DEATHS
	Livebirths	Stillbirths	Early neonatal	Neonatal	Postneonatal	
All causes	690 013	3598	1716	2207	982	3189
Congenital anomalies		557	413	595	362	957
Antepartum infections		31	33	64	6	70
Immaturity			1026	1241	187	1428
Asphyxia, anoxia, trauma		91	204	224	8	232
External conditions		7	2	6	43	49
Infections			10	26	97	123
Other specific conditions		2	13	19	24	43
Antepartum asphyxia		912				–
Remaining antepartum deaths		1732				–
Sudden infant deaths			3	11	144	155
Other conditions		66	12	21	111	132

(Adapted from Office of National Statistics data: www.statistics.gov.uk.)

many other things determine these outcomes. The only way to determine the effect of vasodilators on these outcomes is within a randomised controlled trial where comparison groups are tightly matched.

Services should regularly monitor quality aspects of care and it is recommended that these are published as an annual report. Ideally these data would be collated on a regional or national basis and there are excellent examples of this (Fig. 2.8). The minimal content of an annual report has been defined (British Association of

Perinatal Medicine 1996) and should also include the monitoring of the rates of disability in defined groups of survivors (see Ch. 3 and Fig. 3.4).

The audit cycle

The audit cycle (Fig. 2.5) comprises a series of processes needed to integrate the results of audit into clinical practice. The identification of topics for audit may be defined within the neonatal team in

Fig. 2.7 Stillbirths and neonatal death rates 2000–2008 for singletons and twin births in England, Wales, Northern Ireland and crown dependencies. (Data from Centre for Maternal and Child Enquiries (2010).)

response to an observation that prompts the initiation of the investigation or the topic may be identified by health commissioners (mortality and disability rates) or regionally/nationally. The American Academy of Pediatrics issues regular statements of policy or guidance that may form the basis for audit. In the UK the medical Royal Colleges have established audit groups and formulate guidance in the specialty. Within neonatology both the RCPCH (www.rcpch.ac.uk – Clinical Effectiveness) and Royal College of Obstetricians and Gynaecologists (www.rcog.org.uk – Good Practice) produce guidance of relevance to neonatal practice, but globally within the UK there are few national neonatal guidelines.

Despite huge investment by the NHS, audit has not won the hearts and minds of many doctors. Part of this is the failure to understand the importance of a scientific base to the collection, analysis and interpretation of audit data, which is as important in the audit process as it is in research. Appropriate support for audit is often not available locally, in terms of either staffing levels or expertise, but investment in the clinical governance process has improved the situation widely over the past 5 years. Correctly supported and executed, audit may make an important contribution to the success of a neonatal service.

Much audit is achieved by examining medical case records. Ideally prospective data collection should be established as variations in recording information may render the audit dataset incomplete. Retrospective audit from case notes should recognise its limitations but it remains an important part of the process. Problems that occur in retrospective and (to a lesser extent) in prospective audit data collection are:

- bias due to poor diagnostic coding
- bias in record retrieval (difficulty in identifying cases, particularly if they have died)
- bias relating to sample size
- reliability of audit data (e.g. variation in recording or definition between patients and errors in filing of investigation results in notes)
- bias due to missing information
- inadequate capture of 'non-routine' data to be used in audit
- case mix and comorbidity

- inability to assess qualitative aspects of care: timeliness, coordination, empathic components and appropriateness.

A good audit design will address these deficiencies in the planning stage and thereby avoid major errors. It will also include and involve staff from outside the immediate neonatal team, who are critical to its success. Once the results are available the critical decision is which of the (any) changes in management that flow from the audit are to be effected. The line of action and responsibility for implementation should be carefully addressed. Financial consequences of audit/changes in practice must be identified and early managerial involvement in implementation is clearly crucial to the success of a project. Medical and nursing education and training for staff in support services must include the development of skills in the audit process.

Finally the audit cycle is a continuous loop: once an audit is complete and the recommendations implemented further audit should be planned to ensure the success of these changes.

Benchmarking

A 'benchmark' was originally a surveying mark placed to allow repeated measurements using a levelling staff; it is thus a point of reference, criterion or touchstone (*Oxford English Dictionary* 1989). The process of assessing the structure, process or outcome of a service against an externally derived standard is often termed 'benchmarking', in contrast to audit, which is carried out in response to locally derived standards. In effect they are similar processes carried out to different reference points.

Within the professional neonatal community a range of initiatives are designed to benchmark performance against that of other services, regional/network-based groups (e.g. the Trent Neonatal Survey; the Thames Perinatal Group Accreditation Scheme), national initiatives (e.g. the National Neonatal Audit: <http://www.rcpch.ac.uk/Research/ce/Clinical-Audit/NNAP>) or internationally, using schemes such as the Vermont Oxford Network (www.vtoxford.org) or EuroNeoNet (www.euroneostat.org). One advantage of such schemes is that ongoing benchmarking can identify areas for service improvement strategies, in initiatives such as the Vermont Oxford Network NICQ and the UK National Patient Safety Agency Safer Neonatal Practice programmes (www.nrls.npsa.nhs.uk/resources/clinical-specialty/paediatrics-and-child-health).

Other aspects of clinical governance

Like medical audit, there is a danger that clinical governance will be applied 'top-down' and therefore become irrelevant to many of the staff. Over recent years several hospitals across the UK have encouraged the development of shared governance – a system of encouraging ownership, widening involvement and engagement. With its origins in the US health community, there are several models which have evolved (*Burnhope and Edmonstone* 2003). Although this is often seen as a nursing development 'which seeks to grant nursing staff control over their professional practice and develop and make a genuine contribution to the wider corporate agenda' (*Gavin et al.* 1999), the principles can and probably should be extended to multidisciplinary teams such as those that work in neonatal care. Retention and recruitment of nursing staff can be materially enhanced by the inclusion of all grades of staff, enhancing acceptance of responsibility for the service, improving communication and respecting time spent in developing the shared governance process. This process demands a fundamental reappraisal of neonatal teams and is not a 'quick fix' or panacea to aid a failing system.

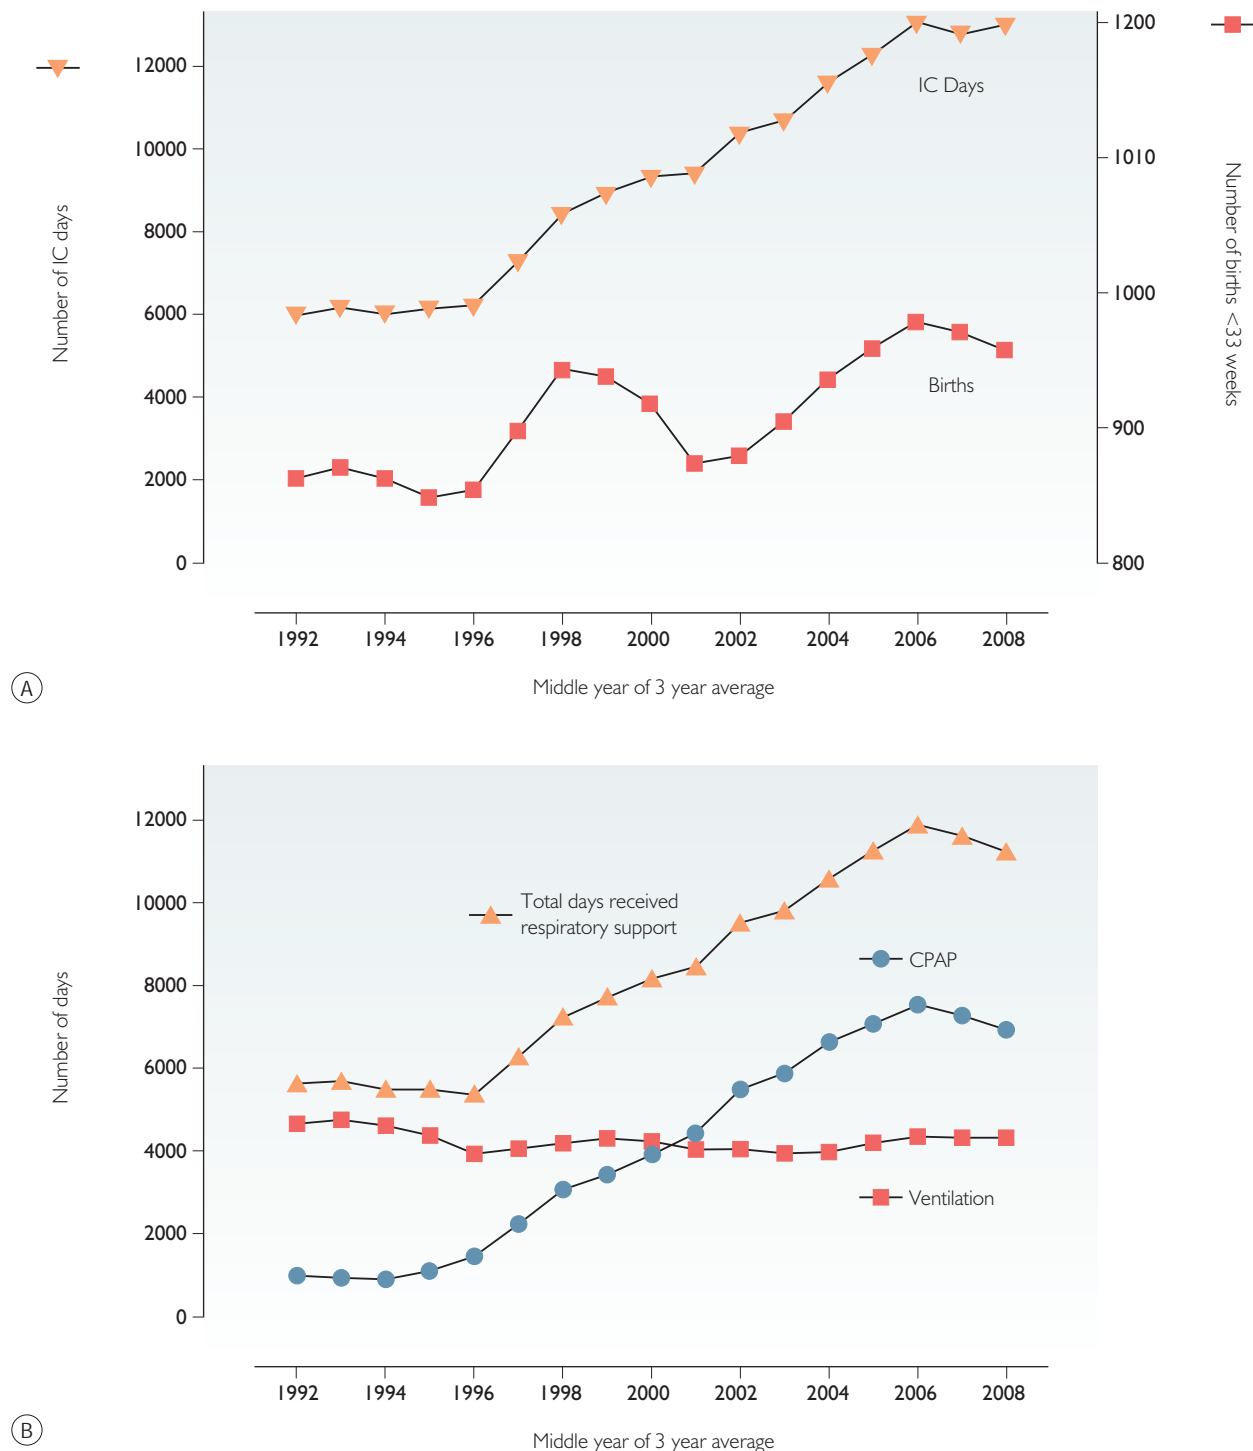

Fig. 2.8 Trent neonatal data.

In a UK health service increasingly driven by elective targets, clinical governance provides a method by which acute services can ensure that their configuration and resources are not passed by. NHS trusts have widely accepted a risk management approach and this needs to be stated and addressed or accepted by the corporate structure. Increasingly, neonatal care is being addressed by a range of corporate agenda such as corporate benchmarking, meeting of standards to

minimise the risk of litigation and standard pricing. External reviews of service by NHS-sponsored bodies, such as the Audit Commission, the Clinical Standards Advisory Group, the Department of Health External Review Group and Neonatal Taskforce ([Report of the Neonatal Intensive Care Services Review 2009](#)), have been regularly published over the past 10 years. The effect that these initiatives have on the delivery of neonatal care remains to be seen.

Box 2.2 Examples of family-friendly standards for the neonatal intensive care unit

Where admission to a neonatal unit is predicted, a prenatal opportunity to visit the neonatal unit and meet key personnel should be offered to the family

All parents should be introduced to facilities, routines, staff and equipment on admission to a neonatal unit

Every parent should have unrestricted access to his or her baby, unless individual restrictions can be justified in the baby's best interest

Parents should be encouraged and supported to participate in decision-making about the care and treatment of their baby. Written and regularly updated care plans should be shared with parents. Clinical care decisions, including end-of-life decisions, should be made by experienced staff in partnership with the parents and discussions held in an appropriate setting

Parents are encouraged and supported to participate in their baby's care at the earliest opportunity, including:

Regular skin-to-skin care

Providing comforting touch, comfort holding, particularly during painful procedures

Feeding

Day-to-day care, such as nappy changing

Every baby should be treated with dignity and respect:

Appropriate positioning is promoted and encouraged

Clinical interventions are managed to minimise stress, avoid pain and conserve energy

Noise and light levels are managed to minimise stress

Appropriate clothing is used at all times, taking into account parents' choice

Privacy is respected and promoted as appropriate to the baby's condition

All parents will have the opportunity to discuss their baby's diagnosis and care with a senior clinician within 24 hours following admission or a significant change in condition

Written information should be available (in languages and formats appropriate to the local community) to all users of the service on medical and surgical treatments, to permit early and effective communication with parents covering at least:

Condition/diagnosis

Treatment options available

Likely outcomes/benefits of treatment

Possible complications/risks

Possible tests and investigations

Whom to contact with queries or for advice

Where to go for further information, including useful websites

Circumstances requiring consent (written and verbal)

Maternity and neonatal services should encourage breastfeeding and the expression of milk through the provision of information and dedicated support, including:

Whenever possible, initiation of breastfeeding as soon as possible after birth

When necessary, support to start expression as soon after delivery as the mother's condition allows to maximise the benefit of colostrum

The availability of a comfortable, dedicated and discreet area

The facility to express discreetly at the cotside

The availability of breast pumps and associated equipment for every mother who requires them

Supporting breastfeeding as part of the discharge process

Promotion of safe and hygienic handling and storage of breast milk

Possible availability of donor breast milk

(Adapted from Report of the Neonatal Intensive Care Services Review (2009). A Toolkit for Quality Neonatal Services. Department of Health and the Bliss Baby Charter Standards, London. (2009))

Standards and perinatal audit tools

Standards

How do we know that our neonatal services are performing well? This may be done through two main processes – firstly, information is collected about the service and, secondly, a set of quality indicators is used to check that we are performing to a standard. Actually, this is done in reverse, as, once an indicator is defined, the data are then collected to demonstrate performance, or the data collected may not be appropriate. Neonatal services are also expected to be evaluated against a range of local professional health organisation standards, such as record-keeping, as are all other hospital-based areas, but here we consider specific neonatal standards.

The first quality standards for NIC in the UK were published in 1996 and updated in 2001. Where possible statements were based on published evidence but it was recognised that for many none existed. Detailed recommendations covered service size, medical and nurse staffing, support staff, equipment, audit and continuing education within neonatal care. As part of a new Department of Health and NHS initiative, the Neonatal Taskforce, these were redeveloped using a much broader stakeholder base, including parent groups, and are published as an appendix to the *Toolkit for High Quality Neonatal Services* (Report of the Neonatal Intensive Care

Services Review 2009). In this are defined principles or characteristics of a quality service, including organisation, staffing, care of the baby and family experience, transfers, professional competence, education and training, neonatal surgery, clinical governance and data requirements. These are further supported by a revision of the professional standards (British Association of Perinatal Medicine 2010) and have been distilled as National Institute for Health and Clinical Excellence (NICE) *Quality Standards* (NICE 2010). As these reports have only recently been produced it is too early to tell how they will drive service development but for the first time in the UK we have a set of standards that are agreed between service users, providers and managers. An example of standards for family-friendly care is shown in Box 2.2.

Definitions – mortality and morbidity

Conventionally, birthweight is subdivided into low birthweight (LBW: <2501 g), very low birthweight (VLBW: <1501 g) and extremely low birthweight (ELBW: <1001 g). Similar groupings are often used for preterm gestations but there is little agreement as to the definition of very preterm (birth at either ≤30 weeks or ≤32

Fig. 2.9 Primary cause for neonatal deaths 2006 using the Centre for Maternal and Child Enquiries neonatal classification, England and Wales, Northern Ireland and crown dependencies 2008. (Redrawn from Centre for Maternal and Child Enquiries Perinatal Mortality to 2008. Centre for Maternal and Child Enquiries 2010, London)

weeks) or extremely preterm (usually birth at 25 or less weeks of gestation). These broad categories are based on risk of death and perinatal complications.

Definition of the causes of perinatal and infant death may help to understand the relationship between specific causes and developments in healthcare. One such classification is that proposed by Wigglesworth, which has been used to classify deaths over several

years as part of the Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI), that has been recently modified (Fig. 2.9) (Centre for Maternal and Child Enquiries 2010). Much of the fall in postneonatal infant mortality has been due to a reduction in the proportion of children ascribed to the sudden infant death syndrome (SIDS) category, initially over the 1980s because of improvements in pathological practice and better diagnosis and then during

Box 2.3 International Federation of Gynecology and Obstetrics (FIGO) recommendations for the international collection of perinatal mortality statistics

Data collection

Collect numbers of births ≥ 500 g birthweight, early and late neonatal deaths (≤ 28 days) and identify stillbirths and neonatal deaths with lethal malformations or with birthweight < 1000 g

Perinatal statistics

Lethal malformation rate per 1000 births

Stillbirth rate (SBR) per 1000 births

Neonatal mortality rate (NMR) per 1000 livebirths (livebirths dying up to and including 28 days after birth)

Perinatal mortality rate (PNMR) per 1000 births (stillbirths plus livebirths dying up to and including 7 days after birth)

Excluding lethal malformations (include all birthweights)

SBR, NMR, PNMR

Excluding lethal malformations and births < 1000 g birthweight

SBR, NMR, PNMR

Excluding births < 1000 g birthweight (including lethal malformations)

SBR, NMR, PNMR

the 1990s following the observation that prone lying was associated with SIDS (Fleming et al. 1990), alongside intercurrent illness and parental smoking.

The International Federation of Gynecology and Obstetrics (FIGO) and World Health Organization have defined datasets to facilitate international comparison of neonatal and perinatal morbidity (Box 2.3). In particular the definitions and methods of reporting data recommended by FIGO allow correction for major differences in neonatal service provision, presenting the information as totals and then excluding babies with lethal malformations and those of greater than 1000 g birthweight.

Although these classifications are very helpful on an international stage, providing benchmarking for developing health communities, within a highly developed health service mortality and morbidity at lower gestations and weights have become of equal importance.

Mortality and morbidity rates are critically dependent on the definition of the baseline population and reports of poor outcomes must be clear in their definition for their interpretation and comparison with other reports. For example, a report of outcome for very preterm children will have differing mortality rates if only babies who are admitted for intensive care are considered from a report where all liveborn babies are included, as the latter also includes delivery-room deaths and the former may include postnatal transfers. It is important to attribute deaths appropriately to the unit or population from which the infant derived and not to the unit to which they were transferred. In the EPICure study, livebirth at 20–25 completed weeks of gestation was used and the effect of simply using babies who were admitted for neonatal care results in significantly improved survival rates (Wood et al. 2000). However even this is potentially biased due to differences in the classification of a livebirth and probably the most useful starting point is the

Table 2.4 World Health Organization international classification of impairments, disabilities and handicaps

Impairment	Any loss or abnormality of psychological, physiological or anatomical structure or function
Disability	Any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being
Handicap	A disadvantage for a given individual, resulting from an impairment or a disability, that limits or prevents the fulfilment of a role that is normal (depending on age, sex and social and cultural factors) for that individual

population of fetuses who have an audible heart beat at the onset of labour or elective delivery. Babies born at or after 26 weeks of gestation rarely die in the delivery room and differences between outcomes based on babies alive at onset of labour, livebirths or admissions for care become less important.

The definition, use and interpretation of longer term morbidity data are discussed in Chapter 3. The use of standardised definitions of disability (Table 3.2) enhances the ability to benchmark outcomes in one population against another and is to be encouraged. Current international definitions (Table 2.4) have undergone re-evaluation to include broader issues of participation and inclusion but for outcome studies these original definitions suffice (Ch. 3). Historically these data have been collected in high-risk populations by neonatal teams but ideally this information should be available from routine systems to provide a global picture of impairment using the Child Health Computer system or local disability registers. In such situations it is clear that the vast majority of impairment and disability in the community occurs in children who were born at or near full term but birthweight or gestational age-specific rates of disability increase as birthweight and gestation fall. Attempts to harness parental or non-clinical assessment to improve data collection have not been entirely successful.

Neonatal data recording

Population data

Statutory registration of birth and death provides an opportunity for universal data collection that may be targeted at information gathering or to provide ongoing data for subsequent healthcare, e.g. child health systems. This provides basic data in terms of gestation at birth, birthweight, sex and survival. In the UK these have been brought together to provide a comprehensive picture of population variation and trends. Standardisation of more detailed data collection is still not achieved across the UK despite initiatives to enhance it. In the smaller population of Scotland, the SMR-11 birth data collection form has provided an excellent source of population-based information. The development of the rapid reporting form for perinatal death by the CESDI has facilitated a range of investigations into perinatal death and presently continues as an important source of information (www.cemach.org.uk) (see below).

Box 2.4 Summary of current recommended British Association for Perinatal Medicine neonatal dataset (2004)**Patient-based data items****Static data items**

Name/code of hospital
 Mother's NHS number
 Postcode of mother's residence at birth
 Planned place of delivery at booking
 Place of birth
 Baby's NHS number
 Date and time of birth
 Source of admission to the unit
 Date and time of admission
 Birthweight
 Best estimate of gestation at delivery
 Sex
 Number of fetuses and birth order
 Mother received antenatal steroids
 Date of discharge, transfer or death
 Time of death
 Discharge or transfer destination
 Whether postmortem performed
 Weight at discharge home
 Head circumference at discharge home
 Tube feeding at discharge home
 Oxygen at discharge home
 Surfactant therapy
 Chest drain for pulmonary air leak
 Date of first retinopathy of prematurity (ROP) screen
 Treatment for ROP
 Cerebral ultrasound (as per local policy)
 Hearing screening (as per local policy)
 Shunt surgery for hydrocephalus
 Surgery for patent ductus arteriosus
 Surgery for necrotising enterocolitis

Daily data items (yes/no except daily weight)

Current weight
 Endotracheal tube in situ
 Treated with nasal continuous positive airway pressure
 Recurrent apnoea requiring frequent (more than 5 in 24 hours) interventions
 Intra-arterial or central venous (including umbilical) line in situ
 Received:
 Supplemental oxygen

Surfactant
 Full or partial exchange transfusion
 Peritoneal dialysis
 Inotrope, pulmonary vasodilator or prostaglandin
 One-to-one nursing care
 Any parenteral nutrition
 Treatment for convulsions

Unit-based data items**Static data items (annual summary)***Number of:*

Consultants with ≥ 6 neonatal sessions
 ANNP/nurse consultants in the unit
 Support staff (includes senior nurse manager, ward manager, outreach nurses, family care team, quality and research nurses)

Presence of:

Senior nurse with managerial responsibility
 Nurse responsible for further education
 Family care team available
 Transport service available
 Physiotherapist, speech therapist, dietician, pharmacist available

Other pressures:

Average (% whole-time equivalent) annual sickness rate
 Percentage own staff on maternity leave

Daily data items*Number of:*

Nurses involved in direct clinical care with a specialty qualification in neonatal care
 Nurses (excluding students) involved in clinical care without specialty
 Nursing students
 Own staff doing extra shifts
 Number extra nurses supplied from agency

Presence of:

Resident senior house officer or ANNP with sole responsibility to the neonatal unit
 Resident middle-grade cover from a doctor or ANNP
 Middle grade with sole responsibility for the neonatal unit
 Consultant available during the day with sole responsibility to the neonatal unit
 Consultant on call out of hours with sole responsibility to the neonatal unit

ANNP, advanced neonatal nurse practitioner.

High-risk groups

Statutory recording of data concerning the receipt of NIC is the route by which hospitals are reimbursed for their neonatal unit activity in the National Minimum Data Set (NMDS). These data are collected on a daily basis and provide each hospital with a common process audit. Beyond this there is no system for more structured data collection. Most neonatal services now use a common data platform based on the BAPM Neonatal Dataset (www.bapm.org/publications) using one of three systems (Box 2.4). These are

collated in hospital and network reports. As part of the national drive to acquire reliable and useful neonatal data the National Neonatal Audit Project collects a restricted dataset to determine performance to target in several areas of care provision (Watkinson and Davis 2009).

As an example of good practice, the Australian and New Zealand Neonatal Network has collated information from 22 NICUs from 1994 for babies <32 weeks of gestation or <1500 g birthweight (www.usyd.edu.au/cphsr/anznn). All units are part of a highly developed, regionalised system with centralised care and

Fig. 2.10 Australia and New Zealand Neonatal Network: survival to discharge by gestational age (with 95% confidence interval). (Data from Donoghue and the ANZNN Executive (2009).)

well-organised neonatal retrieval services. In the first report of this collaboration they identified four main objectives:

1. To provide a core dataset that will:
 - a. identify trends and variations in mortality and morbidity which warrant further study
 - b. enhance the ability to carry out multicentre studies and randomised trials
 - c. provide information on neonatal outcomes adjusted for case mix and disease severity to assist with quality improvement.
2. To monitor the use of new technologies.
3. To develop and evaluate a risk score for babies in the network.
4. To develop and assess clinical indicators for perinatal care through neonatal outcomes.

The most recent report (Donoghue and the ANZNN Executive 2009) indicates that most of these aims have been met and that the information provides an excellent set of data against which other neonatal services can be benchmarked. The network also acts as a facilitator for a range of academic activities to ensure that care and outcome continue to improve. The critical mass provided by such collaboration produces narrow confidence intervals for important outcomes (Fig. 2.10).

A further example of international collaboration in this field is the Vermont Oxford Network (www.vtoxford.org). Initially designed to collect and collate patient-based information to facilitate inter-unit comparisons, it now receives data from over 850 neonatal units worldwide and records information on over 50 000 infants, including datasets from over 50% of NICUs in the USA and units in 26 other countries. A smaller international collaboration, EuroPeriStat, is currently evaluating care and implementing quality programmes

in the European Union (www.europeristat.com) as part of an initiative to reduce inequality in outcomes across the European Union.

Guidelines and evidence-based care

Perinatal care is one area of modern medicine which has embraced the concept of the randomised controlled trial and thus in many areas it is possible to base care on secure scientific evidence. The collation of these results has allowed a number of statements to be made about good practice in a wide range of areas, brought together in the Cochrane Collaboration. Neonatal reviews are freely available (www.nichd.nih.gov/cochrane/neonatal). Not all areas of practice are however covered by such reviews and clinical practice must take account of a much broader range of evidence and personal experience. Although national and professional bodies may produce guidance for good practice from time to time, clear information is required in the context of the working environment and the local development of guidelines is necessary. The establishment of managed clinical networks poses an opportunity for these to be developed on a network basis, reducing the workload for an individual unit and ensuring a more even delivery of quality care.

Guidelines are not mandatory protocols. Care must be individually tailored to the individual's clinical needs and it may thus be necessary to deviate from unit guidelines if it is deemed necessary in a particular situation. However, default management plans are possible for many areas of care and it is primarily in these areas of care that guidelines make a valuable contribution to good practice.

When guidelines are drawn up it is helpful to identify audit points and methods of audit so that prospective data collection against the standards set may be made.

The process of integrating scientific evidence into practice has been adopted widely as the practice of evidence-based medicine. A full description of this process is outside the remit of this chapter (www.cebm.net). However, the processes of asking answerable questions, assembling and critically appraising the evidence, acting on the evidence and establishing performance against the evidence are central to the audit/guideline philosophy.

Within a single service it is often difficult to demonstrate benefit from the introduction of evidence-based changes in management. Working together as a local network will clearly bring advantages in terms of population size but using the powerful resources of a large organisation such as the Vermont Oxford Network allows a more rapid introduction of change from a broader range of services.

As part of the NICQ 2000 scheme the Vermont Oxford Network facilitated a range of service quality improvements in the areas of nosocomial infection, chronic lung disease, postnatal dexamethasone use, prevention of brain haemorrhage and ischaemic brain injury and family-centred care. This is the first time that such an undertaking has been attempted in the field of clinical care. Each service improvement occurred across a group of neonatal units with variable success. The success of this scheme provides powerful evidence that a facilitated approach, using common methodology across a network of units and evidence-based changes in practice, can be implemented and audited.

In the UK the most effective audit process has been the CESDI. Registered deaths from 20 weeks of gestation until the end of the first postnatal year are reported centrally. Within this system a series of confidential structured enquiries have been organised, each focused around a different theme to identify both avoidable factors and good practice in the management of reported cases. For example, this process was supplemented by the collection of a comparison group of surviving children born at 27 and 28 completed weeks of gestation to provide a national case-control study of factors associated with death (Acolet et al. 2005). The report from this powerful evaluation of practice has important implications for neonatal practice in the UK.

Conclusions

Within a modern health service, neonatal care makes an important contribution to the health of the population, providing critical care support to babies who are seriously ill and taking evidence-based measures to avoid illness and unnecessary intervention. NIC has developed greatly over the past 30 years with demonstrable improvements in survival and morbidity. Organisation of what are now complex services must be demonstrated to be clinically and financially efficient and clinical care must be transparent and evidence-based. These are challenges that are met though clinical governance and service improvement, as described above. These are now key areas of neonatal practice and central to the delivery of improved outcomes in the future.

The ex-preterm young adult	84

Pregnancies deliver prematurely because of problems with the fetus, the mother or the intrauterine environment; in each of these situations fetal health is compromised before birth and it is perhaps unsurprising that many such children develop later problems, particularly following very preterm birth before 32 weeks of gestation. This period from the middle of the second trimester into the first month of the third trimester is associated with rapid organ growth and development. In the brain, although neuronal migration is mainly complete, cortical structure evolves rapidly and there are

important structural elements that develop in this critical period. The processes surrounding preterm birth may interrupt neuronal or oligodendroglial migration and cortical structural development. Furthermore, we understand little of how our clinical care and the effects of the neonatal intensive care unit (NICU) environment interact positively or negatively with these processes. It is, therefore, encouraging that the great majority of survivors develop appropriately and enjoy a good quality of life though to adulthood (Hack et al. 2002; McCormick and Richardson 2002; Cooke 2004; Saigal et al. 2006), but others do develop a range of impairments that interfere with health or education and lead to problems that persist throughout the lifespan. It is these who are the focus of this chapter.

History: early neonatal care

Interest in the care of the newborn has waxed and waned through history. The invention that marked the dawn of 'modern' neonatal care was the incubator, first credited to a French obstetrician, Stéphane Tarnier, derived from an agricultural device to hatch hens' eggs. The introduction into the Paris Maternité hospital in 1878 facilitated the development of the ideas published by Pierre Budin in his classic monograph entitled *Le Nourissant (The Nursling)* (Budin 1907). Although mainly concerned with inpatient care, there is one surviving photograph of his 'graduates'.

Martin Couney, a pupil of Budin, requested a chance to exhibit the new incubators in the World Exposition in Berlin in 1896. Permission granted, he conceived the idea of a live exhibit with babies, otherwise destined to die, from a local charitable hospital. These *Kinderbrutanstltdter* (child hatcheries) proved a great success and were soon imitated across the world. Couney himself settled in Cooney Island, where his exhibitions became famous; his own daughter was born prematurely and incubated for 3 months (Silverman 1979).

Couney's influence led Julius Hess to establish the eight-cot premature baby station at the Sarah Morris Hospital, Chicago. This rapidly expanded and led to the first reliable reports of survival and outcome (Hess 1934). No significant deviation from normal term controls was noted in this highly selected population and no effects of birthweight, gestation, sex or maternal illness were found on outcome. Indeed, Gesell and Armatruda (1947), using graduates of Couney's summer exhibitions, concluded: 'prematurity does not

Fig. 3.1 Outcome studies for babies of <1501 g birthweight pooled by quinquennium to show the percentage of babies who died and survived, with and without handicap. (Redrawn from Stewart et al. (1981).)

markedly alter the normal course of mental growth. It neither retards nor accelerates. However, thinking was soon to change.

Over the next decade the importance of the length of gestation was appreciated and increased morbidity in the smaller survivors was noted, leading to questions about care for these vulnerable babies which persist right through to today. For example, Sheridan (1962) observed that improvements in mortality had 'been accompanied by a rising survival of immature, malformed, birth injured and weakly babies' and Drillien (1958) warned that improvements in care might lead to increasing numbers of handicapped children in the community.

Care had up to this point been crude, as exemplified by the uncertainty surrounding the use of oxygen (Cross 1973), but the 1960s heralded the start of more careful and considered interventions such as early feeding with breast milk and more appropriate respiratory interventions. There were conflicting reports as to trends in outcomes during this time. The first important systematic attempt to review trends in outcome for very-low-birthweight (VLBW) births was published by Stewart and colleagues (1981). They indicated some of the difficulties in comparing reports, often from specialist centres reporting selected groups of infants. They summarised outcome from published reports as death, handicapped or healthy survivor and averaged over adjacent 5-year periods over 32 years. From 1960 mortality was found to have fallen progressively, but in each epoch 6–8% of total livebirths had handicaps (Fig. 3.1). There was no evidence, therefore, of an excess of handicapped children in the community as a result of these improvements in care. The same trends applied equally to the subgroup <1000 g birthweight.

The contribution of prematurity to disability in the community

The notion that increased survival brought an additional burden of disability into the population remains even today. The concept of a 'gain' in a healthy survivor is set against a 'loss' as a child with

disability. Overall, the gain in terms of healthy survivors far outweighs the increasing burden of disability in the population. Since the early 1980s there has been an explosion of interest in this area and a huge literature base has evolved. Over short periods of time it is clear that trends in disability rates are hard to demonstrate but mortality has continued to decrease as the gestational age at which birth is considered of borderline viability has fallen, generally without increasing the proportion of survivors with handicap or disability.

The increasing anxiety surrounding the provision of care for the baby of borderline viability persists even today (Nuffield Council on Bioethics 2006) and is now directed to babies born before 25 weeks of gestation, such is survival at later gestational ages. Survival at these low gestations is in part determined by the attitudes of caregivers, some centres preferring not to offer care at these low gestations in the belief that outcome is likely to be so poor that to attempt intensive care is considered wrong. Very few studies have attempted to define the results of different models of care. One important study compares the outcome in a health service with near-universal initiation of intensive care in the USA against selective initiation in the Netherlands; this resulted in 24.1 additional survivors and 7.2 additional cases of cerebral palsy (CP) for each 100 livebirths (Lorenz et al. 2001). Thus the gain and loss account is still in favour of intensive care if CP is used as an outcome; many would argue that cognitive and behavioural impairment is an even more important adverse outcome measure, but one for which the appropriate study has not been done.

Improving survival has been recognised in the UK by the reduction in gestational age for the definition of stillbirth in 1992 from 28 to 24 weeks. Furthermore, as we will see, although most survivors are free of major handicapping conditions, many more subtle (and less easy to predict) conditions in the fields of learning, motor skills and behaviour are now apparent in survivors, closely related to the degree of immaturity at birth. For these more subtle conditions, as for serious disability such as CP, there is a close relationship to gestational age (Fig. 3.2). However it must be emphasised that preterm birth only occurs in a small proportion of the population (6–13% in different countries) and that the groups most often studied with the highest prevalence of disability (very preterm or extremely preterm births) constitute less than 1% of all births. Therefore, the population-attributable risk for all of these conditions is highest in term-born children, followed by late and moderate preterm children and lowest for the very/extremely preterm groups. For example, in terms of special educational needs (SEN), the population-attributable percentage for births 24–27 weeks was 5%, for 28–32 weeks 11%, for 33–36 weeks 20% and 65% from births at full term (MacKay et al. 2010).

Reporting outcomes and study design

Data concerning the progress of neonatal intensive care graduates can be used as part of an ongoing audit of outcome or as part of a hypothesis-based research study. Such a study may explore factors that influence development or developmental trajectories (e.g. social or nutritional factors) or the predictive value of particular observations (e.g. cranial ultrasound appearances). Increasingly, randomised trials of neonatal interventions are including longer term outcomes (usually at 18–24 months) as secondary or even primary outcomes for a range of neonatal treatments and in economic appraisals of such. In an ideal world these would be collected in an agreed fashion for all children using routine systems, but this is as yet not possible.

Fig. 3.2 Percentage of children with special educational needs by gestational age at delivery (note the logarithmic scale). (Redrawn from MacKay et al. (2010).)

Comparing studies in this area is fraught with methodological problems that often preclude comparison of outcome statistics between studies, despite attempts to do so (see below). It is important, therefore, that the data are presented as fully as possible to facilitate comparison year on year and between studies. Reports of population outcomes should contain as a minimum:

- information on the birth population
 - all births or livebirths in a given geographic population
 - numbers of babies admitted for neonatal intensive care
 - details of transfers for care (in and ex utero)
 - survivors to discharge home
- information on the selection and composition of a comparator population, if applicable
- age at assessment (with range) and correction for prematurity if applied
- proportion of the population assessed and reasons for non-assessment – a diagram similar to that recommended for randomised trials in the CONSORT statement (Schulz et al. 2010) is often the clearest way of displaying this
- measures used to define the performance of a population (e.g. intelligence test), definitions of categories and methods used to classify outcome and the numbers with disability in each domain of outcome (e.g. CP, cognitive function, hearing or visual impairment).

This requirement applies less to targeted studies of interventions but nonetheless the discipline of identifying the sample used by reporting the population as suggested above allows much better understanding of the applicability of the results of studies to routine practice. More detailed descriptions of the requirements for such studies have been published (Kiely and Paneth 1981; Mutch et al. 1989; for a series of reviews see Marlow 2006) and general reporting

requirements for cohort studies should be adhered to (von Elm et al. 2007).

In 1994, because of a lack of consistency between studies in definitions for long-term outcomes, guidelines for the categorisation of severely impaired outcome following prematurity were developed in the UK (Anonymous 1995). This was the outcome that was felt to be best predictive of later ongoing disability and ascertainment at 2 years was chosen as the age at which serious CP could be identified with some confidence, bearing in mind the difficulty in interpreting very early assessments. More recently this has been revised to include categories of severe and moderate impairment in both neurodevelopmental and somatic domains (Table 3.1) (Report of a BAPM/RCPCH Working Group 2008). This simple functional classification should serve as a minimum basis for reporting outcomes for preterm populations and may be easily incorporated in routine clinical follow-up. Alongside this the prevalence of CP (see below) should be reported.

There is less consensus regarding the definition of disability at later ages. Formal definitions of impairment, disability and handicap are still very useful and should underpin any scheme (Ch. 2, Table 2.7). However, these definitions have recently been revised to include broader categories of impairment, activity limitations and participation restrictions within society in the International Classification of Function, Disability and Health (ICF), which, although more relevant to society and individuals, makes simple categorisation for outcome studies much less clear.

In pragmatic terms it is usual to continue to categorise impairment across the domains shown in Table 3.1, but with the addition of behaviour (using a relevant behavioural scale) and the inclusion of the Manual Abilities Classification System (Eliasson et al. 2006) alongside the Gross Motor Function Classification System (Palisano et al. 1997). Categorisation on continuous outcomes using

Table 3.1 Summary of definitions for reporting severe and moderate neurodevelopmental disability at 2 years; these may be combined as a single category of neurodevelopmental impairment (NDI), plus additional criteria for other disabilities

CRITERIA FOR DOMAIN	SEVERE NEURODEVELOPMENTAL DISABILITY	MODERATE NEURODEVELOPMENTAL DISABILITY
	Any one of the below	Any one of the below
Motor	Cerebral palsy with GMFCS level 3, 4 or 5	Cerebral palsy with GMFCS level 2
Cognitive function	Score < -3 SD below norm (DQ <55)	Score -2 SD to -3 SD below norm (DQ 55–70)
Hearing	No useful hearing even with aids (profound >90 dB HL)	Hearing loss corrected with aids (usually moderate 40–70 dB HL) or Some hearing loss not corrected by aids (usually severe 70–90 dB HL)
Speech and language	No meaningful words/signs or Unable to comprehend cued command (i.e. commands only understood in a familiar situation or with visual cues, e.g. gestures)	Some, but fewer than five, words or signs or Unable to comprehend uncued command but able to comprehend a cued command
Vision	Blind or Can only perceive light or light-reflecting objects	Seems to have moderately reduced vision but better than severe visual impairment or Blind in one eye with good vision in the contralateral eye
Other disabilities (included as additional impairments to SND or NDI)		
Respiratory	Requires continued respiratory support or oxygen	Limited exercise tolerance
Gastrointestinal	Requires TPN, NG or PEG feeding	On special diet or has stoma
Renal	Requires dialysis or awaiting organ transplant	Renal impairment requiring treatment or special diet
(Modified from Report of a BAPM/RCPCH Working Group (2008).) DQ, Developmental Quotient; GMFCS, Gross Motor Function Classification System; HL, hearing loss; NG, nasogastric; PEG, percutaneous endoscopic gastrostomy; TPN, total parenteral nutrition.		

standard deviation bands (-1 to -2 SD; -2 to -3 SD; < -3 SD) to denote, respectively, mild, moderate and severely impaired outcomes is conventional. The use of standardised outcome measures (e.g. cognitive, neurological, motor or behavioural domains) differs widely and, to a large extent, depends upon the hypothesis under investigation. Where there are clear internationally accepted definitions (e.g. Diagnostic and Statistical Manual of Mental Disorders, 4th ed. (DSM-IV)), these should be reported alongside results on measures specific to the individual study. However the research hypothesis will determine the choice and selection of investigation required and the selection of such tests has been discussed in reviews (Salt and Redshaw 2006; Johnson 2007).

Research evaluations in childhood should still, where possible, be focused on a population base, as described above, and data reported in a standardised fashion. The importance of recruiting contemporary comparison groups is stressed as secular upward drifts in IQ scores are well described (Flynn 1999) and the results of categorisation of children's performance will depend on which reference norms are selected with older measures (Wolke et al. 1994). More recently, changes in test structure and standardisation, for example in the new third edition of the Bayley Scales (Bayley-III: Anderson et al. 2010), have made this more important.

The importance of attempting to examine or at least obtain classifying information on all children in a population as far as possible has been stressed. There is some evidence that the non-responders

may comprise an excess of severely disabled children (Wolke et al. 1995; Tin et al. 1998; Johnson et al. 2009a), although there is a paucity of data from other studies to support this. Increasingly the issue of research governance and the necessity to respect parents' privacy means that fewer attempts to contact parents for follow-up investigations are justifiable and research ethics committees are mindful to limit these. Difficulties with contacting parents after some time means that the taking of consent for later research evaluations should be done at the point of original entry into the study and contact maintained with newsletters, birthday cards or similar, as this should help to minimise loss to follow-up.

Outcome in early infancy

Motor development

Schemes for neurological examination of the newborn, such as those of Amiel-Tison, Dubowitz and Prechtl, are described in Chapter 40 part 1. Neonatologists must be aware of the different patterns of development over the first year and, where supported by evidence, be prepared to embrace a range of interventions in the nursery and after discharge to optimise a child's development.

Despite the reliance on ultrasound-detected brain lesions for prognosis, clinical assessment of the infant at discharge is of at least

equal importance to evaluating the results of cranial imaging. Amiel-Tison and Grenier (1986) have described a simple functional examination to be performed at around 40 weeks' postmenstrual age. At this age, the very preterm baby is quite different from a newborn term infant, particularly if born at a very low gestational age at birth. Ex-preterm babies are more visually active and demonstrate less flexion and more extensor activity. When the examination is optimal and the results of cranial ultrasound show no abnormality, the risk of abnormality at 12 months of age is negligible (Roth et al. 1993). The positive predictive value is less useful as many babies will eventually lose their non-optimal signs early in the first year.

The very preterm baby is hypotonic and weak, with a poorly calcified skeleton. These impart particular vulnerability to external influences on the development of neurological tone and to skeletal deformations. Nursing postures may lead to changes in head and chest shape if they are not varied and prone positioning will encourage extensor posturing and external hip rotation with shortening of the hip adductors (Amiel-Tison and Grenier 1986). This may encourage hip dislocation if the child develops spasticity but may easily be avoided using simple postural management (Downs et al. 1991). The recent interest in nursing positioning will facilitate normal postural development for very preterm infants. Long-term ventilation and chronic lung disease are associated with similar positional issues; neck retraction and truncal extension are features of airway-shortening manoeuvres. Irritability associated with these deformities produces a picture that may be attributed to neurological injury and handling or feeding children with fixed postural deformity is difficult and may lead to problems in maternal attachment.

These influences may all modify the trajectory of development. de Groot and colleagues (1995) have described a group of ex-preterm infants with discrepancies between active and passive muscle tone that are most obvious in the extensor muscles of the trunk and may also be asymmetric (de Groot et al. 1997b). This usually transient dystonia may be a feature of the developing ex-preterm infant independent of positional changes. de Groot and colleagues argue that these tonal abnormalities lead to delay in unsupported sitting and rotation towards the end of the first year. These have implications for transition between postures and also lead to delay in fine motor development (de Groot et al. 1997a, b) and behavioural changes, through impairment of ability to optimise gross motor and hand function in an otherwise normal child because of truncal fixation.

Transient dystonia was described in preterm children by Drillien (1972) as infants with an excess of extensor hypertonicity in the trunk and legs, increased hip adductor tone and delayed supporting reactions. Such changes tend to resolve at around the child's first birthday or over the second year and be initially diagnosed as CP. Other more recent studies have evaluated motor development over the first 18 months. Pederson and colleagues (2000) studied a geographically based cohort of babies <2000 g birthweight. They categorised 29% as dystonic, 10% as hypotonic and 8% as suspected CP. The prevalence of dystonia was 35% in babies <1000 g, 35% for those of 1000–1499 g and 21% in babies 1500–1999 g. The peak prevalence of dystonia was at 7 months of age corrected for prematurity. Of children at 18 months of age with suspected CP, when examined at 7 months, five had been labelled as suspect CP, eight dystonia and one hypotonia. In another study the prevalence of dystonia was 36% of 260 VLBW infants (Pallas Alonso et al. 2000). In a further study, although truncal hyperextension had disappeared by 24–26 months of age, associated abnormalities of arm and hand function appeared to persist, perhaps as precursors of later motor abnormalities (de Vries and de Groot 2002).

Four studies have indicated long-term outcomes for dystonic infants. In Drillien's (1980) original study they were found to have an excess of educational difficulties; in a study of 50 children there was a trend towards more neuromotor difficulties (Sommerfelt et al. 1996); and in a further study dystonic infants had lower cognitive scores and higher disability grades at early school age (Khadilkar et al. 1993).

Cerebral palsy

The definition of CP has been updated to include wider aspects of function (Rosenbaum et al. 2007):

Cerebral palsy describes a group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, perception, cognition, communication, and behaviour, by epilepsy, and by secondary musculoskeletal problems.

William Little is credited with the observation that cerebral spasticity and paralysis were caused by 'difficulties arising around the time of birth', including preterm birth (and asphyxia), hence the epithet 'Little's disease' applied to diplegia. The specific association between a broad category of bilateral spasticity, which he termed spastic diplegia, and prematurity was first formally described in a paper entitled 'Zum Cerablen Diplegien' published in 1896 by Sigmund Freud, during his work as a paediatric neurologist with Charcot in Paris (Accardo 1982). Thus the increased risk of CP following preterm birth has been known for some time and, indeed, CP is often considered to be the most common and important disability following preterm birth. In fact this is not the case as developmental delay and cognitive impairments are by far the commonest disabilities. Nonetheless CP remains one of the most important outcomes and in the early 1980s spastic diplegia was used as a marker of the success of perinatal services (Hagberg et al. 1996).

The risk of CP is inversely related to gestational age at birth and increased in the presence of fetal growth restriction, at least among moderately preterm children (Blair and Stanley 1990), although the use of fetal growth standards instead of birthweight standards indicates a consistent relationship between prevalence of CP and size at birth across the gestational range (Fig. 3.3) (Jarvis et al. 2003). As many older studies are birthweight-based, the results must be treated with some caution because of the varying proportion of babies born after fetal growth restriction (Ch. 10). Thus the evaluation of secular trends in CP must be related to either birthweight or gestation because of the close links. The evolution of birthweight-specific trends in the prevalence of CP over the time period of introduction of neonatal intensive care in Merseyside, UK, has been described (Pharoah et al. 1996). As birthweight-specific survival increased there was an initial rise in the prevalence of CP within that birthweight band followed by a levelling out. This may relate to the increasing survival of children with CP who would otherwise have died, up to an equilibrium point.

Population trends in the prevalence of CP as a group or in birthweight-specific groupings are difficult to interpret, although towards the late 1990s the rate of CP appeared to be decreasing in Sweden (Himmelman et al. 2005) and in the Surveillance for Cerebral Palsy in Europe (SCPE) collaboration of CP registers there was a fall in CP prevalence for babies 28–32 weeks from 1981 to 1995 but little change for babies <28 weeks (Fig. 3.4) (Platt et al. 2007). Furthermore, data from the 4Child Register of CP in four UK

counties seem to indicate a falling off in CP prevalence for births of less than 28 weeks of gestation through to 2001–2003, demonstrating the value of longitudinal data (Fig. 3.5). These findings are consistent with low prevalence in three recent reports of extremely preterm children from Victoria, Australia (2005: 9.8% 22–27 weeks' gestation: Doyle et al. 2010), from Edmonton, Canada (2000–2003: 1.9% <27 weeks: Robertson et al. 2007) and Cleveland, OH, USA (2000–02: 5% <1000 g birthweight: Wilson-Costello et al. 2005).

The distribution of impairment in CP is determined by the pattern of brain injury. Diplegia, in which the impairment is more

severe caudally, is considered to be the result of damage to the internal capsule as part of periventricular leukomalacia. This usually symmetrical lesion is commonly observed on magnetic resonance imaging (MRI) scans at follow-up even if no neonatal ultrasound evidence of injury was observed (Childs et al. 2001). Diplegia is often associated with relatively mild disability and there is often less severe impairment in other domains compared with other patterns of CP. In the EPICure cohort of babies of 25 weeks' gestational age or less, only 44% (12/27) of children with diplegia had severe disability and thus were likely to have persisting disability at later ages (Wood et al. 2000).

Spastic hemiplegia, where the distribution of impairment is the reverse of diplegia and where there is usually significant asymmetry, results from lesions involving the cortex, such as cerebral venous infarction accompanying germinal matrix and intraventricular haemorrhage. Spastic quadriplegia, where there is four-limb involvement equally distributed in upper and lower limbs, occurs in variable proportions in reports. The distribution of disability in children with diplegia and hemiplegia is not always confined to the legs or to one side of the body and it is a subjective decision as to how to categorise the impairments. This accounts for many of the differences found between different observers. However, the impairment in quadriplegia is more extensive than in the other two and the disability is frequently severe (11/12 in the EPICure cohort). Other types of CP are found less frequently in very preterm populations.

In the discussions of classification of CP the above categories provide a sensible aetiologically relevant categorisation. However, over the years the classification has changed to reflect the prevailing fashion (Morris 2007). Most recently the SCPE group has published a classification and an algorithm, which should be used in future classifications based on three groupings (Table 3.2).

The timing of diagnosis in follow-up reports is important in determining the prevalence of CP; the predictive value of a label of CP increases as the child grows up. There is some consensus that the diagnosis of CP producing significant disability is usually accurate by the age of 2 years (Johnson 1995), but that, before that, abnormal patterns of motor development and dystonia or developmental delay may confuse the unwary. In the National Collaborative Perinatal Project CP was overdiagnosed at 12 months compared with assessment at 7 years, such that half of the children with the

Table 3.2 Categorisation of cerebral palsy based on clinical features

Spastic cerebral palsy

Characterised by at least two of:

- Abnormal pattern of posture and/or movement
- Increased tone (not necessarily constantly)
- Pathological reflexes (hyperreflexia or pyramidal signs, e.g. Babinski response)
 - It may be unilateral (hemiplegia) or bilateral

Ataxic cerebral palsy

Characterised by both of:

- Abnormal pattern of posture and/or movement
- Loss of orderly muscular coordination, so that movements are performed with abnormal force, rhythm and accuracy

Dyskinetic cerebral palsy

Characterised by both of:

- Abnormal pattern of posture and/or movement
- Involuntary, uncontrolled, recurring, occasionally stereotyped movements of affected body parts

Dyskinetic cerebral palsy may be either:

- Dystonic cerebral palsy, dominated by both hypokinesia and hypertonia
- Choreaathetotic cerebral palsy, dominated by both hyperkinesia and hypotonia

(Reproduced from http://www-rheop.ujf-grenoble.fr/scpe2/site_scpe: see website for further details.)

Despite the recommendation to wait until 2 years, even at this age there is overdiagnosis (Doyle 2001) and some less severe impairment may not be detectable until early school age (Astbury et al. 1990).

Careful sequential neonatal cerebral ultrasound scanning may identify the majority of children who go on to develop severe CP (de Vries et al. 2004) (Ch. 40.5) and early sequential neuroassessment in infancy is mandatory if CP is to be identified and managed appropriately. The role of other specific investigations is less clear; for example, somatosensory evoked potentials (Pike and Marlow 2000) and Prechtl's assessment of general movements (Einspieler and Prechtl 2005) are good predictors of outcome but have not found a place in routine practice as they are time-consuming and require great skill to do.

Screening vision and hearing

Screening for retinopathy of prematurity (ROP) is addressed in Chapter 33, but this cannot form the basis for screening for visual or ocular impairments. Squints and refractive errors are frequently found at follow-up in infancy and later childhood, thus each assessment must include adequate examination of visual activity and ocular movements. Refractive errors and subtle disorders of vision such as poor stereognosis and contrast sensitivity are found frequently at longer term follow-up (Pennefather et al. 1995; Powls et al. 1997; O'Connor et al. 2002; Johnson et al. 2009a), and should be sought in assessments at school age. In a teenage follow-up of the East Midlands cohort of children who had been screened but not treated for ROP, ophthalmic morbidity was found in 67.8% of children born ≤ 1000 g, 51.6% of those 1001–1250 g, 44.3% of those 1251–1500 g and 49.5% of those 1501–1750 g compared with 19.5% of their comparison group (O'Connor et al. 2002).

Sensorineural hearing loss is more prevalent in preterm populations, although the aetiology is still obscure and may well be multifactorial (Marlow et al. 2000). Found in 1–4% of VLBW children, this represents a 10-fold increase over unselected populations (Marlow et al. 2000; Hille et al. 2007; Robertson et al. 2009; Coenraad et al. 2010). Because of this, most services have developed targeted neonatal screening policies in which prematurity (either

diagnosis at 1 year were free of neurological signs 6 years later (Nelson and Ellenberg 1982). The most common types of CP to resolve were categorised as mild and were of the monoparetic, dyskinetic or diplegic types; resolution was more frequent in black infants. However a significant proportion of the children in whom signs had resolved (13% white and 25% blacks) had an IQ ≤ 70 at 7 years, emphasising the importance of careful early examination.

as VLBW or birth ≤ 32 weeks) is included in the screened population alongside children with a family history of deafness, orofacial anomalies and perinatal central nervous system infection. More recently there has been a move towards universal neonatal hearing screening, predicated on the thesis that early intervention for children with severe or profound hearing loss may improve later language and speech development (Yoshinaga-Itano et al. 1998). Most targeted screening involves automated or manual evoked responses (auditory or brainstem response (ABR)) that will identify children with significant hearing loss. Universal screening in the USA and most European countries involves testing with automated ABR technology, whereas currently in the UK a 'two-step' approach has been adopted using initial screening with otoacoustic emissions and automated ABR for failures. Universal screening has a sensitivity of between 80% and 90% and a specificity of above 90% (Davies 1997) and the median age of detection of severe hearing loss may be as low as 2 months, facilitating early intervention.

Developmental progress

Central to the definition of disability in preterm populations is an estimate of the child's developmental level. Correction of age for prematurity is usually applied up to 2 years, but may be extended to 3 years for extremely preterm children where the correction still makes around 10% difference depending on gestational age (Fig. 3.6). This correction is controversial, as some prefer to assess against chronological age-related norms, claiming that this more correctly identifies those with developmental problems, but as increasingly immature children survive this has fallen out of practice. Correcting for prematurity once the child is in the education system, where he or she is compared with peers, is generally deemed unnecessary.

Clinic assessment using one of the widely available developmental screening tools (e.g. Denver Developmental Screening Test or Schedule of Growing Skills) may indicate normal or very abnormal progress but the diagnostic utility and predictive value are not known; in particular, screening tests are used to identify children for more detailed assessment and are likely to overidentify children with developmental problems.

Most services now evaluate development with a formal assessment using one of the available test instruments. Any scale with

which the assessor is familiar may be used in clinical practice but the commonest ones in current use are the Bayley Scales of Infant and Toddler Development (Bayley-III) and the Griffiths Scales (second edition). Both have had recent standardisations which enhance the value of the results but the Bayley-III was restructured and rescaled in a new manner and this has resulted in relatively high scores (+7 points compared with the second edition – the BSID-II), which makes scores difficult to interpret. Most observers have found that fewer children are identified as low scorers using these scales and recommend that all new preterm cohort studies recruit contemporary term-born comparison children (Anderson et al. 2010), which will add greatly to the logistics and cost of doing such studies. The predictive value of individual developmental score results into childhood is relatively weak, although preterm children appear to track better than normal term-born children. However, in population studies the predictive value of proportions in different outcome categories is much better, hence these scores are useful in categorising outcomes for research purposes. The Bayley-III scales have no values for very poorly performing children (scores < -3 SD) and nominal scores must then be allocated to children who perform below the lower level of the test range; this must be acknowledged in reports as even allocating a score of 50 may produce very different results from allocating a score of -4 SD (40), as is often done.

Using the BSID-II, 30% of the EPICure cohort had scores < 70 and 11% < 55 , representing -2 and -3 SD respectively. Scores were lower in boys but did not vary with gestational age or plurality (Wood et al. 2000). Mean scores were MDI (Mental Development Index) 82 (SD 15) and PDI (Psychomotor Development Index) 83 (SD 16) for those tested but 9.5% of the children assessed failed to complete the BSID-II. Evaluating mean scores of various studies is fraught with difficulty, mainly because exclusions can seriously modify results. It is important to include the whole population in any assessment where possible or to describe why children fail to complete the test.

A formal developmental assessment is expensive and time-consuming for service or research purposes, particularly where a categorisation around one figure is required. Increasingly, 18–24-month assessments are being used as outcome measures for randomised trials and their inclusion adds very significantly to the cost of the project. We have recently validated an adapted parent report questionnaire (Saudino et al. 1998) against the BSID-II at 2 years in very preterm children (Johnson et al. 2003, 2004, 2008; Johnson and Marlow 2011a). This has high correlation ($r = 0.68$) and good diagnostic utility (sensitivity 81%; specificity 81%) for a BSID-II cognitive score < 70 and is likely to be as accurate as repeating the developmental assessment with another observer. This has proved a useful tool in the routine follow-up of preterm populations and has been used in multicentre trials, where follow-up is important to the evaluation of the safety and efficacy of an intervention but there are cost constraints. Although the potential cost of overreferrals may be a cause for concern for clinical use of such parental questionnaires, we have shown that very preterm infants with false-positive screens are at greater risk for neurodevelopmental and behavioural problems than those with true negative results and further assessment may be warranted (Johnson et al. 2008).

There are no particular patterns of developmental impairments associated with prematurity, rather as a group scores are globally depressed; this reflects the perhaps surprising lack of specific learning impairments at later ages. Behavioural difficulties are particularly difficult to evaluate in infancy but the knowledge that attention-deficit hyperactivity disorder (ADHD) is a persistent and constant finding in later studies encourages assessment in infancy. Sadly there are no well-respected measures which help to identify

Fig. 3.6 Percentage deficit in developmental terms produced by using chronological age rather than corrected age for 24- and 28-week babies.

children at risk, although direct observation in the clinic does seem to identify a significant proportion of children with inattention and distractibility (Astbury et al. 1990).

Current follow-up practice

Our present practice in University College Hospital is to review children in the multidisciplinary neonatal follow-up clinic until 2 years corrected for prematurity, if they fall into one of three distinct high-risk groups, namely babies of 28 weeks' gestation or less, babies with bronchopulmonary dysplasia and babies who have demonstrated neonatal encephalopathy. Review is by a neonatologist, respiratory nurse, dietician and speech and language therapist, neurologist and a developmental specialist. Children are seen approximately 3-monthly over the first year and then at 2 years. Annual review visits for those with bronchopulmonary dysplasia then are offered until 5 years. A formal neurological assessment (Amiel-Tison and Grenier 1986; Haataja et al. 2001) is done at each visit together with a Bayley-III assessment. Video analysis of general movements (Prechtl et al. 1997) is carried out at 12 weeks postterm. Babies with identified developmental or neurological issues are referred to their local neurodisability team for assessment and intervention.

It should be stressed that this is an environment where we have good community-based family support from health visitors, primary care physicians and community paediatric staff. There is also good support from and easy access to advice from dietetics and locality-based physiotherapy and other family support teams for children

with special needs. In other health systems alternative arrangements may be necessary.

Predicting disability in preterm infants

The major determinants of later disability are in essence similar to those predicting perinatal death, often described as part of the continuum of reproductive casualty (Sameroff and Chandler 1975). Perinatal factors increasing risk of disability include male sex (Kraemer 2000; Wood et al. 2000), gestational age and birthweight.

Using simple data such as these one can make broad statements about disability-free survival, which can help inform decisions around the time of birth (Fig. 3.7) (Tyson et al. 2008). A more specific prognosis for serious disability may be derived from brain imaging using ultrasound, MRI or neurosensory assessments (Ch. 40.5) and used to counsel parents on an individual risk basis.

Interventions to improve outcomes for very preterm babies

Children with or at risk of evolving disabilities should be referred for specialist neuroassessment and treatment. However, the knowledge that developmental and cognitive disadvantage is associated with preterm birth has prompted several important efforts to provide developmental or educational therapy for children without overt disabilities. Many of the strategies stem from early attempts

Fig. 3.7 Observed and maximum potential rates of survival without profound impairment at 18–22 months by sex, birthweight and gestational week. (Redrawn from Tyson et al. (2008).)

to enhance developmental outcome for children with Down syndrome. Although referral to early education schemes is commonplace, the evidence that these or similar schemes provide benefit in the long term is wanting (Anonymous 1990, 1998; Spittle et al. 2007, 2009; Koldewijn et al. 2010). Nonetheless these schemes may be essential methods of supporting families who are particularly disadvantaged, in whom there are without doubt impressive short-term gains, particularly in the families of heavier and more mature preterm children (Anonymous 1990), but the evidence for long-term benefit in terms of cognitive and learning ability is still lacking (McCarton et al. 1997).

School-age outcomes

There is some degree of continuity across childhood for those with the most severe impairment (Fig. 3.7) and for the most immature children there remains a significant risk of disability even as they enter adolescence. However much of the adverse outcome for such children is dependent upon cognitive and behavioural function, which influences schooling and is discussed next.

Cognitive function and school performance

Preterm birth results in significant cognitive disadvantages for surviving populations. Reports over the last 30 years have consistently identified cognitive impairment as the most common disability at school age. As with other outcomes, interpreting results requires close examination of individual studies and an understanding of the methods and measures used. In particular, the selection of IQ test, criteria for classifying impairment and exclusion of children who are unable to complete assessments affect the reported prevalence of impairment. Although the substitution of a nominal IQ score to quantify performance in those with severe impairment ultimately yields a higher prevalence of impairment, it provides a more accurate estimate of the totality of cognitive deficit for population-based investigations.

The vast majority of studies of very preterm survivors report significantly lower IQ scores than term peers (Johnson 2007). Group mean scores may be within the normal range (-1 sd) and thus the inclusion of a term reference group is crucial for identifying and interpreting the clinical significance of results. In a meta-analysis using pooled data from 1556 very preterm children and 1720 controls born in 1975–1988, Bhutta and colleagues (2002) reported an overall weighted mean difference of 10.9 IQ points (95% confidence interval 9.2–12.5) equating to a 0.73 sd deficit. The results were not affected by age at assessment, country of birth or by hospital versus population-based data, but, as would be expected, the greatest deficits were found in studies in which children with neurosensory impairments were included.

Follow-up data from cohorts born in the 1990s onwards continue to highlight the high prevalence of cognitive impairment in middle childhood despite major advances in neonatal intensive care over this period (Anderson and Doyle 2003; Hack et al. 2005; Fily et al. 2006; Johnson et al. 2009a). A number of studies have also identified a significantly increased risk of cognitive impairment in boys compared with girls, particularly for extremely preterm survivors (Brothwood et al. 1986; Hintz et al. 2006; Johnson et al. 2009a), a finding common to functional domains.

The gestational age-related gradient in outcomes is no more evident than in the domain of cognition. In the Bavarian Longitudinal Study there was no relationship between gestational age and IQ at 33 weeks' gestation or more, but there was a progressive reduction in scores for each week from 32 to 27 weeks (Wolke et al.

Fig. 3.8 Prevalence of disability among evaluated children born at 25 weeks of gestation or less in 1995 at 2.5, 6 and 11 years of age (the EPICure study). (Redrawn from Johnson et al. (2009a).)

2001). This represents an average deficit of approximately 2.5 IQ points per week ≤ 32 weeks and would predict a 20-point deficit for babies of 24 weeks' gestation. Consideration of the EPICure study 6-year assessment results, which used the same IQ test, confirms this prediction (Fig. 3.8). As gestational age is a major factor in defining outcome the interpretation of test scores for birthweight-defined cohorts becomes much more difficult.

Follow-up studies have become increasingly multidisciplinary in nature and it is now evident that preterm children are at particular risk for a range of neuropsychological deficits including visuospatial impairments, sensorimotor processing difficulties and deficits in a range of attention and executive functions which have been shown to confer additional functional deficit over low IQ alone (Bohm et al. 2002, 2004; Anderson and Doyle 2004; Marlow et al. 2007; Mulder et al. 2010). Executive functions may be considered an umbrella term for higher order cognitive processes required for purposeful, goal-directed behaviour and comprise skills such as working memory, inhibition, planning, shifting, fluency and processing speed. Although these skills are highly task-dependent, making comparisons between studies particularly problematic, two recent meta-analyses have shown that these are specific areas of deficit in preterm populations and that, like IQ, they are associated with gestational age (Aarnoudse-Moens et al. 2009; Mulder et al. 2009).

These skills play a key role in learning and school performance (Bull and Scerif 2001; St Clair-Thompson and Gathercole 2006). It is therefore unsurprising that, although the majority of preterm children attend mainstream schools, they have poorer academic attainment across the national curriculum than their term-born classmates, even among those who are free of neurosensory and cognitive impairment (Botting et al. 1998; Schneider et al. 2004; Litt et al. 2005; Aarnoudse-Moens et al. 2009; Johnson et al. 2009c; Johnson and Marlow 2011a). Of all the subjects studied at school, preterm children have particular difficulties with mathematics and the majority of learning difficulties observed are within this domain (Klebanov et al. 1994; Johnson et al. 2009c; Taylor et al. 2009; Johnson and Marlow 2011a). Unlike problems with reading, mathematics difficulties appear to be specific learning disabilities that are not accounted for by poor cognitive ability.

Given these learning difficulties, very preterm children have a significantly higher prevalence of SEN and a markedly greater reliance on learning support than their classmates (Saigal et al. 2003; MacKay et al. 2010). In the EPICure study, 57% of extremely preterm

children in mainstream schools required SEN provision at 11 years of age and 23% had a formal statement of SEN compared with just 1% of their classmates (Johnson et al. 2009c). The need for SEN provision is not confined to those born extremely preterm. Whilst it was traditionally thought that the outcomes of babies born late and moderately preterm (32–26 weeks) were largely the same as those of their term-born counterparts, recent studies have highlighted the increased risk for cognitive and educational deficits in this population (Chyi et al. 2008; MacKay et al. 2010; Mathiasen et al. 2010). Although the prevalence of serious impairment is far lower than in very preterm survivors, the population-attributable risk of SEN presents a greater public health burden (Fig. 3.2).

The prevalence of SEN increases throughout secondary education and thus the number already requiring support at the end of primary education is of concern. Furthermore, the educational disadvantage persists beyond childhood: studies report a significant disadvantage in GCSE results (Pharoah et al. 2003) and a reduced earning potential and participation in higher education (Lindstrom et al. 2007; Hack et al. 2009).

As the UK adopts an age-based school entry system, preterm children born in the summer months may be entered in an academic year earlier than if they had been born at term. There is concern that the effects of preterm birth on school performance are compounded by their relative social and emotional immaturity if entered an academic year earlier. In the EPICure study, we found that children who would have entered school an academic year earlier had comparable attainment with their extremely preterm counterparts but required greater SEN provision (Johnson et al. 2009c). Many parents and clinicians believe that delayed or deferred entry would be advantageous for the child, but systematic, hypothesis-driven research is needed in this area before evidence-based recommendations can be made.

In addition, research is required to understand the nature and origins of learning difficulties in order to identify the key components for population-specific interventions. It is important to recognise that there is no single cognitive phenotype associated with preterm birth. The profile of strengths and limitations will differ

between individual children and careful assessment is thus indicated for all preterm children (Aylward 2002). A routine evaluation by an educational psychologist may be beneficial for these survivors.

Behaviour and psychology

Improved multidisciplinary follow-up has also led to a greater understanding of the behavioural sequelae of prematurity. The majority of studies in this area have used screening questionnaires completed by parents and/or teachers. Most frequently cited in the literature is the Child Behavior Checklist (Fig. 3.9), which is used widely but is relatively long and can appear somewhat negative for the respondent. The Strengths and Difficulties Questionnaire (SDQ) is free to use (www.sdqinfo.org) and is gaining popularity, particularly in the UK, for its brevity and cross-cultural validity.

Using screening questionnaires, almost all studies have shown a significant excess of behaviour problems in very preterm and extremely preterm cohorts with prevalence estimates ranging from 13% to 46%. There is less agreement however for the risk of behavioural morbidity in moderate and late preterm cohorts (see Johnson and Marlow, 2011b, for a review).

When internalising and externalising problems are assessed there appears to be little consensus between studies (Bhutta et al. 2002) but at the subscale level there is far greater consistency. In a cross-cultural comparison of outcomes in four population-based cohorts (Canada, Germany, the Netherlands, USA) of children born <1001 g in 1977–1987, all four cohorts had significantly increased scores for social, thought and attention problems which were elevated by 0.5–1.2 SD relative to controls (Hille et al. 2001). In a more recent study of extremely preterm children in Sweden, a remarkably similar pattern of results was found (Fig. 3.10) (Farooqi 2009). A similar behavioural profile is also identified in studies using the SDQ (Gardner et al. 2004; Indredavik et al. 2005; Samara et al. 2008).

These questionnaires are essentially screening tools and thus they are likely to yield many overreferrals. Indeed, studies using

Fig. 3.9 Mean 'z' or standard deviation scores for eight subscales of the Child Behavior Checklist from five studies (higher scores denote greater impairment); the studies all demonstrate an excess of social, thought and attentional problems among extremely low-birthweight children and Swedish extremely preterm children. (Redrawn from Farooqi (2009).)

Fig. 3.10 Mean (sd) mental processing composite (MPC) of the Kaufman ABC for children in the Bavarian Longitudinal Study (births in 1985) and in the EPICure study (births in 1995). (Data from Wolke et al. (2001).) and in the EPICure study (births in 1995; Data from Marlow et al 2006).

diagnostic psychiatric evaluations yield lower prevalence estimates. Such studies are rare given the cost and logistics of implementing diagnostic tests, but are preferable and enable direct comparisons as outcomes are classified using a standardised nosology (e.g. DSM-IV criteria). In five diagnostic studies, prevalence estimates of 22–28% and associated odds ratios of 3–4 have been reported for psychiatric disorders despite differences in the populations studied (Johnson and Marlow 2011b). When individual disorders are considered, studies have shown an excess of ADHD, emotional disorders and autism spectrum disorders (ASD). However, the comorbidities and clinical presentation of these are different from those of the general population and are indicative of a different causative pathway (Johnson and Marlow 2011b).

ADHD is the most prevalent and frequently studied disorder. Studies have shown a gestational age-related gradient with relative risks of 2.6–2.7 for ADHD in very preterm children (Bhutta et al. 2002; Linnet et al. 2006) and a fourfold increased risk for extremely preterm survivors (Hack et al. 2009; Johnson et al. 2010). In contrast to the general population, the male predominance and frequency of comorbid conduct disorders are not typically observed in preterm populations. Furthermore, preterm children appear to be at greater risk for inattention than hyperactivity/impulsivity, both in term of symptoms and diagnoses (Botting et al. 1997; Hack et al. 2009; Johnson et al. 2010). In the EPICure study we reported that the significant excess of ADHD in extremely preterm children at 11 years was accounted for by a specific risk for ADHD/inattentive-subtype disorders. Hyperactivity in preterm children appears to be accounted for by poor general cognitive ability, but inattention may be an additional specific morbidity related to specific deficits in working memory and processing speed observed in this population (Nadeau et al. 2001).

Perhaps the greatest proliferation of recent interest has focused on the association of ASD with preterm birth. Many clinicians can provide anecdotal evidence of infants in their follow-up clinic with behavioural patterns characteristic of the autism spectrum. Indeed, recent studies using the parent-completed Modified Checklist for Autism in Toddlers (M-CHAT) have reported that up to 25% of very preterm infants screened positive for autistic features

(Limperopoulos et al. 2008; Kuban et al. 2009). This has raised concern regarding a high prevalence of ASD in preterm survivors. However, the specificity of screening in infancy is confounded by the high prevalence of neurodevelopmental delay (Johnson et al. 2009b), particularly where the recommended follow-up M-CHAT interview is not used.

The few diagnostic studies that exist have confirmed the risk for ASD but have reported 1–2% prevalence of ASD in low-birthweight children and 8% prevalence in extremely preterm children (Johnson et al. 2010a), which is remarkably higher than the 0.6% prevalence in the general population. ASD were strongly associated with cognitive impairment and we have drawn parallels with Romanian adoptees who exhibit similar behavioural profiles and who have also experienced highly abnormal early physical and psychosocial environments. Such findings are indicative of a non-genetic, environmental origin in this population. In terms of both ADHD and ASD, the correlates and comorbidities indicate a fundamental underlying problem with brain organisation and development following preterm birth (Johnson and Marlow 2011b). Furthermore, symptoms associated with both disorders have been shown to be generally increased in preterm populations and thus there may be many children with a high level of subthreshold difficulties.

Diagnostic studies have also found a four- to sixfold increased risk for emotional disorders in school-aged children (Johnson and Marlow 2011b). However, it appears that the risk is specific to anxiety and few studies have found a significant association with depression. Although emotional disorders are often associated with poor physical health and female sex in the general population, cognitive impairment was more closely associated with such difficulties in preterm children. Indeed, the majority of children with psychiatric diagnoses in the EPICure study had other associated impairments (Fig. 3.11).

The results of both screening and diagnostic studies have thus highlighted a 'preterm behavioural phenotype' that is associated with inattention, anxiety and social problems. The generally high level of these symptoms means that, even in the absence of diagnosed disorders, many preterm children may present with behavioural problems that do not fulfil diagnostic criteria yet which may

Figure 3.11 Prevalence of psychiatric diagnoses (PD) mapped on to the categories of disability among evaluated 11-year-old children from the EPICure study.

have an impact on everyday function. If these children are not identified during routine neonatal follow-up, difficulties may not be picked up until the child enters school. The preterm child, however, is less likely to be 'hyperactive' in the classroom setting, but is more likely to be anxious or withdrawn and, therefore, less likely to come to the teacher's attention. SEN may thus go unrecognised and become exacerbated throughout schooling. Routine behavioural screening and psychiatric referral if incorporated in neonatal follow-up may therefore be beneficial in reducing the burden of disability in preterm populations.

Motor/neurology

Studies of school-age very preterm children consistently demonstrate poor motor performance in terms of manipulative and gross motor skills. A range of tests can be used but the Movement ABC has been most frequently used to quantify the degree of impairment in this group. In a series of three studies from 6 to 12 years, persistence of motor difficulties was demonstrated (Marlow et al. 1993, 1989b; Powls et al. 1995) and these findings have been replicated in many other studies (Levene et al. 1992; Jongmans et al. 1993). Median scores for the preterm group tend to lie at or outside the 75th percentile for comparison groups. Although a significant disability when in infant school, these impairments are less intrusive and less obvious as teenagers, when motor skills are less prominent aspects of performance.

An alternative approach is to use detailed standardised or semi-standardised neurological assessments, such as the scheme of Touwen (1984). The detection of 'minor neurological' or 'soft' signs correlates well with the more functional assessments (Marlow et al. 1989b).

The high proportion of children with impaired motor skills/minor neurological abnormalities may be considered the mild end of a spectrum of disability of which CP is the extreme expression and have been labelled as 'borderline' or 'minimal' CP (Hadders-Algra et al. 1999). One would predict some correlation with brain injuries but the relationship of either motor skills or minor neurological signs to perinatal events or neonatal ultrasound findings is not clear (Levene et al. 1992; Jongmans et al. 1993). More recent studies have failed to demonstrate a relationship between function and teenage MRI appearances, despite a high rate of abnormal scan findings (Cooke and Abernethy 1999; Stewart et al. 1999).

The motor organisational problems may also be reflected in the high frequency of non-right-handedness and less consistent

laterality seen in preterm populations, which show poor correlation with other impaired outcomes or brain injury (Marlow et al. 1989a; Powls et al. 1996a).

Growth and medical outcomes

Despite the concentration on neurological, cognitive and psychological outcomes, it is important not to forget that other aspects of somatic development are frequently disturbed by very preterm birth. VLBW and very preterm children remain smaller throughout childhood than their peers. This is very marked in extremely preterm children, in whom head growth over the first 3 years remains particularly poor and in whom a slim somatotype persists (Wood et al. 2003). Very long-term growth is only rarely reported. In one study bone age and parental heights of 91 VLBW children were integrated to predict adult height (Powls et al. 1996b). Heights for the VLBW group were lower than matched comparison children. However, TW2 RUS score was also significantly advanced over chronological age, indicating that final height would also be impaired: 17% were predicted to be below the 3rd percentile and 33% below the 10th percentile as adults.

Respiratory outcomes are discussed in Chapter 27 part 3, cardiovascular in Chapter 28 and other medical outcomes, including auditory and ocular outcomes, in Chapters 40.5 and 33.

Function and quality of life in surviving ex-preterm children

Although the literature and foregoing discussion are really concerned with the measurement of performance using narrowly focused cognitive or behavioural assessments, such results are difficult to translate into a comprehensive picture of the function of children within society. To a large extent these integrative aspects of outcome may be more important than focused measures of impairment in determining the progress of a neonatal intensive care survivor through life; indeed, the functional definition of outcome at around 2 years has been recommended as a means of defining outcomes for comparative work (Johnson 1995; Report of a BAPM/RCPCH Working Group 2008).

Once infancy is past, the development of a child progresses over multiple domains and functional performance becomes more difficult to register as a single summative measure, hence the reliance on 'medical disability' (CP, cognitive impairment, sensory loss) as an outcome. The recent revision of the World Health Organization ICF has classified outcomes in health and health-related domains (<http://www.who.int/classifications/icf/en/>). These domains are classified from body, individual and societal perspectives by means of two lists, a list of body functions and structure, and a list of domains of activity and participation, together with a range of environmental factors that may modify the impact of an impairment.

The issue of measuring functional outcomes in perinatal outcome studies has been reviewed by Msall and Tremont (2002). These authors develop the thesis that outcome is assessable and better described in four major domains:

1. impairment (disturbance at organ level)
2. functional limitations of personal activities (self-care, mobility, communication, social interaction)
3. disability in social roles (play, school, work)
4. societal limitations (difficulty in participating imposed by social framework).

There are now a range of measures to support such assessments in childhood, each with its own strengths and limitations (Msall and

Fig. 3.12 Odds ratio for measures of functional limitation (upper panel) and service/aids use for teenage children of <750 g birthweight compared with term comparison children. CI, confidence interval; ELBW, extremely low birthweight. (Redrawn from Hack et al. (2000).)

Tremont 2002). Several studies have evaluated functional measures in the preschool years (<6 years) (Saigal et al. 1990; Msall et al. 1993; Msall and Tremont 2000; Palta et al. 2000). For example, in the survivors of the Cryo-ROP study at 5.5 years, all of <1251 g birthweight, 87% had normal functional skills compared with their non-disabled peers and the rates of severe functional disability (< -4 SD of peers) rose from 3.7% of those without ROP to 26% of those with threshold disease (Msall et al. 2000). Functional status was related to visual status at follow-up; in those with favourable visual status, some disability was found in the domains of self-care (25%), communication (22%), motor (5%) and continence (5%), in contrast to those with poor visual outcomes who had disability in 77%, 66%, 43% and 50% of these domains, respectively. Such a picture can demonstrate the vulnerability imposed by medical impairments and help the understanding of those factors that impart protection against disability. In the USA the concept of 'kindergarten-readiness' provides a multidimensional categorisation that can reflect the overall functioning of the child.

Although preschool and school-age children have been frequently studied, there are fewer studies that have evaluated function in adolescence. Hack and colleagues (2000) evaluated functional outcomes for a group of teenagers born <750 g birthweight, 750–1499 g or at term. For the highest risk group of extremely low-birthweight infants as teenagers, two-thirds accessed non-routine educational or medical services, three-quarters used medication, spectacles or other aids to daily living and 86% demonstrated some functional limitation (Fig. 3.12). The intermediate birthweight group still had significant functional limitation compared with terms but the differences were less marked. That use of medication and contacts with a doctor did not differ significantly between the three groups indicates that the needs of these children are generally outside medical practice. Ongoing service provision for this vulnerable group is an important health issue.

A range of quality-of-life measures is available that have been studied in very preterm children. These range from health-related measures such as the Health Utilities Index (www.healthutilities.com) (Saigal et al. 1996), through self-esteem (Saigal et al. 2002) to more subjective measures (Bjerager et al. 1995). Generally such measures seem to indicate that, whereas health and performance may be considerably worse in the preterm groups, happiness and contentment are not significantly worsened by the presence of disabilities.

Fig. 3.13 Odds ratio for risk-taking behaviours by young adults who were of very low birthweight compared with normal birthweight comparison children. CI, confidence interval. (Redrawn from Hack et al. (2002).)

The ex-preterm young adult

The very first reports of outcome in young adult life are now starting to appear (Hack et al. 2002; Cooke 2004; Saigal et al. 2006). Many of the outcomes are as one might expect from the preceding discussion in terms of lower rates of achievement at school or progression into higher education and higher frequency of low IQ, although the smallest, most immature study from Hamilton, Ontario, Canada, provides the most optimistic outcome and suggests a resilience and adaptation that encourage integration. However, surprisingly, VLBW young adults were found to engage in less risk-taking behaviour, such as the use of alcohol, tobacco or drugs (Hack et al. 2002; Cooke 2004), and tended to be less likely to come into contact with the law (Fig. 3.13) (Hack 2006). Whether this represents resilience on the part of the child-cum-adult to engage socially in an appropriate manner or whether this is the end result of the introversion and attentional deficits seen in many of the studies of psychological outcome remains to be determined (Harrison 2002).

One can conclude from these studies that the subjective consideration of quality of life may rise above the objective, performance-driven consideration of impaired function, which permeates our description of outcomes. Outcome for young adults who were born

very preterm may not be as subjectively bad as is anticipated by the close attention to and concentration on impaired function throughout childhood and the integration of this new generation of survivors into society may be considerably better than anticipated.

Summary	92

Introduction

Increasing numbers of premature infants are surviving thanks to technological advances. Mortality has been dramatically reduced but morbidity remains a challenge (Riley et al. 2008). Follow-up studies on children at school age have shown that they are more likely to have difficulties with attention, fine motor skills and

interpersonal relationships (Saigal et al. 2003; Johnson et al. 2009). Developmental care (more specifically, the Newborn Individualized Developmental Care and Assessment Program (NIDCAP)) has been claimed to improve outcomes (Bhutta et al. 2002; Als et al. 2004). This chapter will describe some of the developmental care practices within the context of the developing brain and the evidence behind these approaches.

Brain development in relation to developmental care

Preterm babies are projected into an alien extrauterine setting at a time when their brains are growing more rapidly than at any other time in their life. Their experience is a contrast between the expected environment of their mother's womb and the feel of their parents' bodies after birth and the comfort of their family and community social group (Hofer 1987).

As is well known, development of the brain is influenced by predetermined genetic processing and endogenous and exogenous stimulation. The genetic processing is largely exempt from external influences as it occurs predominantly in the first 20 weeks of gestation. It is after this that the so-called critical periods of brain development occur when environmental influences shape neuronal connectivity and activity (Liu et al. 2007). In essence, during critical periods the brain requires appropriate sensory input from external influences in order to make appropriate connections.

The neonatal intensive care unit (NICU) does not provide the sensory experience that the premature infant was expecting in terms of type, timing or intensity. Consequently there is the potential for these windows of opportunity to be missed. Furthermore, studies on preterm infants have demonstrated that the dual stress for the baby of maternal separation together with frequent painful procedures or discomfort results in potentially neurotoxic brain-altering events (Anand and Scalzo 2000).

Such research findings emphasise the need to recognise that both family relationships and the care given during the preterm infant's stay in the NICU influence the infant's neurodevelopment. Current thinking is that developmental care should be implemented alongside medical interventions in order to maximise the baby's potential and achieve the best possible outcome.

Developmental care

Developmental care is an umbrella term for a variety of approaches used with preterm infants whilst in NICU. The aim is to adapt the infant's sensory experience of the world positively and involve the family and care team. Developmental care includes modifications of both care-giving practices and the baby's physical environment.

The aim of developmental care is to promote the infant's neurodevelopment through increasing comfort, decreasing stress and promoting sleep. Key points related to the most commonly applied developmental care practices are outlined below.

The nursery environment

Environmental modifications to light and noise are those most commonly considered when the term 'developmental care' is used. Indeed, these aspects are important as they have significant influence on the infant's autonomic stability and have the potential to cause harm (Long et al. 1980).

Light

The development of the central visual system may be disrupted by overstimulation of the eyes. Bright light disrupts release of growth hormone and may prolong the time spent in rapid-eye movement sleep (Duffy et al. 1984). Little is known about the development of circadian rhythms in premature infants. However, it has been demonstrated that babies exposed to periods of cycled versus continuous lighting have longer periods of sleep and are more efficient feeders with improved weight gain (Mann et al. 1996).

Recommendations for modifying the nursery environment to support neurodevelopment include dimming lights whilst maintaining a safe level of accurate clinical observation as well as cycling lighting to simulate day-night patterns (White 2007). Individualised bedside lighting and shielding the infant from light with an incubator cover or blanket are recommended (Als and Mcanulty 2000). At term, the baby requires the opportunity to explore the world visually with adequate levels of lighting. This is vital for continued development of the visual system (Stanley et al. 2008).

Noise

In utero, infants are exposed to sound of 40–60 dB, yet in the NICU sound may exceed 120 dB at times. Loud sound levels are known to cause stress in preterm infants. Moreover, preterm infants are unable to habituate to sound within their environment and, consequently, environmental noise interferes with sleep and creates increased distractibility which persists into childhood (Gray and Philbin 2004).

Developmental care aiming to reduce auditory environmental stimuli includes noise monitors (White 2007), lowering the volume of monitor alarms, covering incubators with thick, padded covers and conducting teaching rounds either in an unobtrusive manner or away from the cot side (Lawhon and Melzar 1988).

Guidelines with recommendations for nursery design, which encompass optimal light and sound levels, have been published in the USA (White 2007).

Family-centred care (FCC)

The family has a pivotal role within developmental care and, to reflect this, the term 'family-centred/supportive care' is used. In this

model, families have unrestricted access to their infant. Different interpretations of this premise vary from providing seats for parents next to their baby's incubator to providing a 'private room' within the nursery for the family. Here, they live with their baby until discharge, fully caring for the child with support from the team, as required (Westrup 2009).

One of the key objectives of FCC is to educate and integrate parents into the newborn intensive care environment and to encourage active participation in their baby's care. Furthermore, it aims to help parents observe and interpret their baby's behavioural needs, thus enhancing relationships. This is particularly important given that preterm infants inevitably have lower levels of signalling (Minde et al. 1983).

Kangaroo mother care (KMC)

Developed 30 years ago, KMC aimed to improve infant survival in the absence of incubators. Whilst wearing only a nappy, the baby is placed between the mother's breasts in a vertical position with head and trunk aligned and limbs flexed, with supportive material binding surrounding both. Heat is transmitted from mother to baby, stabilising the baby's temperature; her breathing provides stimulation for her infant's respiration and the upright positioning helps minimise gastro-oesophageal reflux. Today, KMC involves relatives, fathers and same-sex partners as well as biological mothers (Fig. 4.1).

It has been demonstrated that KMC has a positive effect on state organisation, physiological stability, decreased arousal and increased quiet sleep and neurodevelopment. It facilitates the family's psychological healing, enhances parent–infant bonding and improves lactation (Conde Agudelo and Belizan 2003; Charpak et al. 2005). Maternal benefits include increased self-confidence, less postpartum depression and better ability to respond to and care for her baby during admission and after discharge (Tallandini and Scalembra 2006).

There are published guidelines for the implementation of KMC on ventilated and non-ventilated infants (Charpak et al. 2000).

Fig. 4.1 Twins nursed in kangaroo care fashion by their parents at University College Hospital, London. Kangaroo care is an effective developmental care method that should be available for parents of babies at any gestational age admitted to neonatal units, independently of the level of care they receive.

Incubator environment

Staff can increase the baby's comfort during the lengthy periods the child is cared for in an incubator or cot by adopting relatively simple measures such as the following.

Postural support

Swaddling seems to improve sleep quality and diminish stress and pain responses in the preterm infant and it is suggested that it may also improve neuromuscular development (Short et al. 1996). Comfortable swaddling should avoid limb overextension, overheating or interference with respiratory effort. Alternatively, consideration may be given to positioning as, for example, prone or left side-lying may reduce gastro-oesophageal reflux (Ewer et al. 1999) whereas side-lying may enhance neuromuscular development. Supportive bedding materials, including nests, are used to help the infant maintain head and trunk alignment. The position facilitates the baby's efforts to bring the hands together or to the mouth; these are calming strategies that promote further development.

Chemosensory support

The sensory pathways for both taste and smell develop early in utero with the fetus exposed to the mother's diet via the amniotic fluid (Browne 2008). After birth, the infant shows preferences for these flavours, demonstrating the ability to detect and discriminate smell and taste through physiological and behavioural responsiveness. Smell has been shown to influence positively the quality of the infant's arousal and sleep states and aid the infant's recognition, hence encouraging relationships, particularly maternal. Noxious stimuli can have a negative effect (Bartocci et al. 2001).

Exposing preterm infants to the smell of their mother's amniotic fluid and/or colostrum as soon as possible after delivery may ameliorate the effect of separation and facilitate both bonding and later progression to oral feeding (Schaal et al. 1998). Tastes of expressed breast milk may be incorporated into mouth care even with very preterm infants.

Non-nutritive sucking (NNS)

Considerable research has been devoted to NNS whereby the infant is offered a pacifier most usually during tube feeds or as a comforter during painful procedures. The reported benefits related to NNS include earlier discharge, quicker transition to oral feeds and improved physiological stability during painful interventions, particularly when NNS is combined with expressed breast milk or sucrose (Pinelli and Symington 2005).

Support during cares and procedures

It is easy for parents and staff to appreciate that interventions such as blood sampling or lumbar puncture cause pain and discomfort. It is less readily appreciated that routine care procedures like weighing can also engender stress for the infant. Consideration of the following may provide developmental support.

Timing and pacing of cares

As far as possible, the baby's sleep should be respected and protected given its importance for brain development. Whilst it may be considered advantageous to 'cluster' cares and procedures and then to leave the baby undisturbed, the intensity of the interventions may tax the infant physiologically more than allowing the infant to

rest for a short time between activities, ideally with carer support (Holsti et al. 2005).

Gentle handling

The unborn baby lives in a warm, fluid-filled environment, gently rocked by constant oscillations of amniotic fluid. Caregiving in the NICU can be intrusive, painful and stressful. Gentle handling, avoiding sudden changes in posture, is recommended. Supporting the infant with still hands (containment holding) which are gently enveloping can help the baby endure difficult experiences and recover more quickly, particularly when combined with appropriate pacing of caregiving (Als and Gilkerson 1995). Parental holding in this way is probably the ideal physical contact for the preterm infant. The benefit of massage is disputed and can prove overstimulating for more fragile infants.

Pain

Pain and stress are usually recognised in preterm and term babies using pain scales that include facial expressions and physiological variables like heart rate, respiratory rate, mean blood pressure and changes in skin colour (Ch. 25). Pain can be treated with medication, behavioural approaches or both. Pharmacological strategies to provide pain relief include boluses or continuous infusions of morphine, midazolam or fentanyl for ventilated babies and chloral hydrate or oral sucrose before painful procedures. Behavioural interventions include swaddling, gentle handling, NNS, breastfeeding and KMC (Chermont et al. 2009).

Newborn Individualized Developmental Care and Assessment Program

NIDCAP is a structured comprehensive approach that selects appropriate developmental care methods which are continually adapted to the baby's needs at given times in order to promote development. The family are the baby's main advocates and are integral to care.

Based on Als' synactive theory of development (Als 1982), the preterm baby is viewed as an active and competent individual who has prematurely delivered into an alien environment. The baby's developing competencies are described within the context of five subsystems that emerge and interact in response to internal and external stimuli, each system having the potential to support or disrupt the equilibrium of another. These subsystems are:

1. autonomic/physiological (i.e. heart rate, respiratory rate, colour, gastrointestinal signs)
2. motor (posture, tone, movements)
3. state organisation (sleep, wakefulness, arousal)
4. attentional and interactive (increasing periods of quiet alertness where the infant relates to the environment)
5. self-regulatory (strategies the infant uses to maintain or regain a state of equilibrium).

Signals of competence or challenge within each subsystem are reflected in the infant's behaviour.

NIDCAP aims to reduce the discrepancy between the womb and NICU environment (Als et al. 2004) by:

- taking into account the individual infant's current thresholds of behavioural organisation
- diminishing stress
- supporting each infant's strengths and competencies.

A behavioural summary is written by a highly skilled developmental specialist based on in-depth structured observation of the infant before, during and after care. This highlights the infant's avoidance and approach responses, together with a description of the efforts the baby makes to regain equilibrium when challenged. Recommendations for care are then provided that aim to minimise noxious stimuli and to support the infant's developmental agenda. Thus, the carer adjusts the timing of intervention to respect the baby's sleep/wake patterns and assists the baby during care by pacing procedures and supporting the infant's own efforts at self-regulation (Als and Butler 2008).

Discussion of evidence for developmental care

Single studies comparing preterm infants receiving NIDCAP care versus basic developmental care have shown that NIDCAP infants require significantly fewer days of assisted ventilation, are less likely to develop chronic lung disease, have fewer days on parenteral feeds, have shorter transition to full feeds and better average daily weight gain, are younger at discharge and have fewer cases of necrotising enterocolitis (Als et al. 2003; Symington and Pinelli 2006; Cooper et al. 2007; McAnulty et al. 2009; Peters et al. 2009). They also have fewer developmental problems when tested at different ages and are diagnosed with fewer visual problems. Magnetic resonance imaging (MRI) studies have shown better posterior limb of the internal capsule myelination at term age and more mature right hemisphere and frontal lobe function at 8 years of age. Additionally, higher scores have been recorded on maternal perception of her child and on measures of improved family outcome (Als et al. 2003, 2004; Symington and Pinelli 2006; Cooper et al. 2007; McAnulty et al. 2009; Peters et al. 2009).

In contrast with these studies, a Cochrane review showed evidence of no effect for some outcomes, i.e. length of stay, feeding and growth, and respiratory support when comparing NIDCAP

with controls, findings that were confirmed on an unpublished meta-analysis including the two most recent trials (Ohlsson et al. 2009).

Possible reasons for these conflicting results include methodological issues of the individual studies, short exposure to the intervention, small sample sizes, lack of blinding of outcome assessors and, most importantly, the likely contamination between the two arms under investigation.

No harmful effects from NIDCAP or developmental care interventions have been published to date.

Various issues will need to be addressed if more research is to be conducted in NIDCAP. Further studies involving imaging with functional MRI, for example, would be a good measure by proxy of further development.

Summary

The NICU environment plays a major role in the short- and long-term outcomes of preterm babies. Developmentally supportive care and, more specifically, NIDCAP have been suggested to reduce the adverse impact of this alien environment.

Despite the conflicting evidence, many units around the world have instinctively adopted a range of developmental care strategies. For many, using such approaches to provide gentler care just seems intrinsically 'right'. Whilst at present the most robust scientific evidence indicates that NIDCAP has no significant effect, it appears that there is benefit in individualising developmental care approaches to meet the needs and developmental agenda of the infant. By implementing a few simple measures it is possible to deliver care which shifts from being task-oriented to being baby-led. Adjusting the timing of care procedures to protect sleep, dimming lights, keeping noise to a minimum and promoting kangaroo care for fathers as well as mothers are worthwhile changes which even the busiest NICU can manage most of the time and which will yield rich benefits in terms of parental satisfaction and infant comfort.

Introduction

Having a newborn infant in a neonatal unit is an extremely stressful experience for parents. The mother is usually suffering fatigue and physical discomfort from the delivery. Both parents are anxious. Their hopes and dreams are threatened. The future is uncertain, the path unknown. The couple face a strain on their personal and combined resources and cannot know in advance if they will be equal to the challenge.

The parent's principal preoccupation is the establishment of a relationship with this new member of their family, but conditions are far from ideal. Instead of a 3.5-kg term infant on a postnatal ward, the centre of admiration and congratulations, they have an ill baby, often scrawny, distanced from them by a Perspex barrier. Their own feelings of guilt and helplessness are compounded by the fact that there seems to be no role for them; neonatal nurses and doctors are the caregivers; machines and tests replace parental caresses.

If families are to look back on these days and weeks with satisfaction and look forward constructively to the rest of their lives, the professional team must handle them with care. The aim of this chapter is to offer guidance to less experienced clinicians in order to facilitate the best service the circumstances will allow.

Nothing can substitute for personal experience. All junior staff should watch their seniors in action, and take the opportunity to attend counselling sessions with the parents where possible. These interactions depend to an extent on an intangible chemistry between parent and professional, and this chemistry is strongly influenced by the personalities of both. But much can be learned from observing closely how the discussions progress, noting the apposite phrase which crystallises a moment, the tactics which deflect anger, the way in which trust is reinforced.

Although the doctor and the parents may differ on many fronts – culture, religious belief, social class, life choices, education, expectations – these differences must not be permitted to create insuperable hurdles. The baby is our patient but is the parents' child. The decisions should be the right decisions for this family at this point in their lives. The professional's task is to share medical insight and knowledge whilst respecting parental values and beliefs, working with them to make wise choices on behalf of the child.

The relationship with parents

Initial introductions

Courtesy matters. It is polite and helpful, for example, before meeting either or both of the parents, to establish what their names are and how they prefer to be addressed. Similarly the couple need to know their boundaries, and the doctor should introduce him- or herself, and state his or her role in the team. Shaking hands with both parents at first meeting is symbolic of a future trusting relationship. The overall approach should be one of mutual respect.

Establishing trust

The doctor should always bear in mind the importance of trust. Once lost, it is very hard to regain. And whatever the status or level of experience of the professional, unfounded opinions, unrealistic predictions and false hope undermine confidence.

Before the first interview, the doctor must know any relevant family history, and the details of the pregnancy, labour and delivery. The initial meeting may well take place in the delivery room, with parents who have had only the briefest introduction to their newborn baby. At this stage it is essential to keep things simple. Even for the highly educated, this is no time to be bombarded with complex diagnoses, specialist jargon or intricate pathophysiology. The following example gives basic clear information and may be enough for the first interaction: 'Your baby has come out very early and is very small. His lungs have not yet matured. We have connected him to a ventilator, and he is stable for now. We will tell you much more when you are able to visit the baby unit.'

Questions should be answered honestly. Where doubt exists, professionals should resist the impulse to declare that the baby will be 'fine'. It is much better to reply, 'He's comfortable in his incubator at the moment. But we need to see how he progresses in the next few hours before we can be sure how things will go. We'll keep you informed and I can promise you we won't hide anything from you.'

Roles and responsibilities

Every neonatal unit should have a dedicated counselling room where staff can meet families without fear of interruption. In this room, the parents can be confident that they have the undivided attention of the staff and can have all their concerns addressed. Doctors should take their cue from the family as to the amount they can absorb or tolerate at a given sitting.

Neonatal units often have written protocols about who should conduct interviews. The consultant holds overall responsibility not only for the child's care but also for the interactions with the family. Junior paediatricians should never be in the position of communicating with families beyond their level of experience, though parents appreciate informal interactions from all members of the team. Meetings of a particularly sensitive nature should be conducted by the consultant in the presence of a nurse who is looking after the baby and who has established a rapport with the parents. The junior doctor involved should be encouraged to attend for the benefit of his or her training and as he or she too has had a direct role in the baby's care. Regardless of who is present behind closed doors, the whole team needs to know what is said and decided, in order to facilitate effective teamwork. Thereafter, full and careful documentation is essential.

A primary task for the consultant is that of assessing the full clinical picture as far as it can be known. Good counselling depends on accurate facts and knowledge of the literature. There will often be areas of uncertainty, but if there have been exhaustive efforts to find

out as much as possible, the family will usually respect an honest admission from a senior member of staff of 'I don't know'. A statement such as 'I am confused' does not inspire confidence, but a frank 'There are uncertainties ahead and we can't be sure at this stage how things will go, but we'll continue to discuss everything with you' allows the parent to appreciate the evolving picture. The capacity of the parents to tolerate bad news will vary, but the truth should never be compromised. 'Truth sometimes hurts but deceit hurts more' (Fallowfield 1997).

Teamwork

Managing sick infants well is a team effort. A wise doctor will listen to the parents. They have a unique investment in their child and stand in the most privileged position in relation to the baby. With their focus on one infant, they not infrequently detect subtle but important changes in their child's condition. Staff should give proper attention to such misgivings; they are often correct.

Consent to treatment

The subject of consent is currently fraught with difficulties in the developed world. Until recent years it was assumed that babies admitted to a neonatal unit brought with them implied consent, which allowed staff to carry out any procedure on the baby without obtaining specific consent. A new tension has arisen, partly stemming from a small number of legal cases in which medical staff strayed beyond ethical boundaries to the detriment of the patient. As a result, more and more protocols are being developed demanding that written informed consent be obtained for procedures and treatments (e.g. postnatal steroids), allegedly to protect the child, the parents and the staff. Unfortunately, if genuinely informed consent is to be obtained, each interview between staff and parents must be lengthy in order to do the subject justice. Such interviews erode the time that staff can devote to the child's care, and clearly this could have an adverse effect on prognosis. Should a lumbar puncture be delayed at 03:00 hours while parents, already exhausted, are wakened at home and asked to drive to the neonatal unit for an in depth interview, or should staff be allowed to carry out the procedure and discuss this with the couple during daylight hours?

It would be best to explain to the parents at the time of admission to the unit that every effort will be made to keep them up to date and to seek their permission for procedures, but that urgent situations might, of necessity, preclude such interactions. For a procedure that carries clear risks, consent must be obtained by the practitioner designated to carry it out and who must be qualified to do so. Great care must be taken to explain the nature of the investigation or treatment, the intended benefits and the risks attached. Consent is best obtained from the mother; the father may consent if he has parental rights. (See Ch. 6.2 regarding competence for consent.)

Each neonatal unit should have written guidelines for staff to indicate which procedures require consent to be formally documented on an official form. These are usually major undertakings, such as exchange transfusions and operative procedures including laser treatment for retinopathy of prematurity. The parents should be given a copy of the signed consent form on which the benefits and risks are clearly documented.

Consent for less invasive procedures and treatments which carry minimal risks is traditionally obtained verbally, though it is prudent to document this in the case record. Examples may include immunisations, the administration of vitamin K at birth (specifying by which route), the use of breast milk fortifier, and neonatal screening

investigations such as blood sampling to identify phenylketonuria, hypothyroidism and cystic fibrosis.

Consent for research is outside the scope of this chapter, but is nonetheless an important aspect of neonatal care. Parental claims around lack of informed consent for the Continuous Negative Extrathoracic Pressure (CNEP) trial led to one of the largest inquiries so far in this field in the UK (NHS Executive West Midlands Regional Office 2000). The inquiry and the subsequent report were found to be flawed (Hey and Chalmers 2000) and the report was later withdrawn.

It is known that parental recall of events in the newborn period is unreliable (Hey and Chalmers 2000). This highlights the importance of documenting informed consent for clinical trials and for invasive procedures.

Life and death decision-making

Making crucial decisions on behalf of their baby is one of the most difficult experiences parents ever face. Staff may be understandably anxious about the burden parents may carry and about the potential for guilt (McHaffie and Fowlie 1996). In reality, parents want to be given the opportunity to be active in decision-making and they do not appear to suffer adversely as a result (McHaffie 2001).

For this they require direct and open communication about the child's current condition and prognosis. Information should be provided with a good measure of compassion, avoiding euphemisms, using the words 'death' and 'dying' to help validate the situation (Williams et al. 2008). A 'guided consensus' is an effective way of handling the process (Laing 1989). One approach is for the parents to consider goals for care with the clinician, exploring those which are realistic and those which have little chance of success. In this way, the parents feel their voice is heard and they have a chance to evaluate their hopes against the child's best interest (Royal College of Paediatrics and Child Health & Ethics Advisory Committee 2004). It is critical that, before withdrawal of intensive care takes place, the parents as well as the staff are confident that this action is in the child's best interest.

In most cases, consensus is reached without dissension. However, if either the parents or the staff think that intensive care should continue, then any decision to withdraw should be put on hold pending careful review. Usually, parental uncertainty arises from a failure or reluctance to comprehend fully the gravity of the situation. Continued intensive care brings clarity in the fullness of time. The child will either deteriorate or improve, and the decision is then more straightforward.

It is not the intention of this chapter to explore the ethical issues around withdrawal of neonatal intensive care. These have been developed in previous publications (Warnock 1998; McHaffie et al. 2001a).

The dying baby

There can never be a time when high-quality communication is more important than when a baby is dying. The parents will remember professional sensitivity or insensitivity for the rest of their lives.

In the rare event that a newborn infant collapses and dies without warning, there is little time to build a relationship with the family. The consultant must take control of decision-making and communication. Major priorities are that the child should be free of all distress, with dignity respected, and the family should be encouraged to spend the last minutes holding their dying child, free from the encumbrances of intensive care. Helping them to acknowledge their own unique role, to accept the reality of the child's short life

and death and to be involved with the baby after death will facilitate the creation of memories, which can comfort and sustain them in the ensuing years (McHaffie 2001).

Much more commonly, babies die in a neonatal unit after some time and following a deliberate reorientation of care to comfort measures. The parents have had time to get to know the staff, and have been closely involved in decision-making.

Caring for an infant's death

The consultant and a senior nurse should explore with the parents what their wishes may be. Parents may need guidance as to what options are available, and here senior nursing staff may be especially sensitive. Knowing what the options are – to invite close family members and friends to 'say goodbye', organise a baptismal or blessing service, involve siblings, take photographs, collect mementoes, hold and groom the baby, even perhaps take the baby home – enables parents to decide what is right for them and minimises later regret. Tolerances and preferences as to the exact nature of their own involvement vary, but it is important for clinicians to be non-judgemental of parents (McHaffie 2001).

In times of crisis, there can be a great need for spiritual guidance. Religious figures can help parents observe specific rituals where possible, which have the potential to bring comfort to the family, including the choice of burial and funeral services available (Williams et al. 2008).

The way the death is managed will materially influence parental satisfaction and acceptance of the wisdom of the choices made. Staff should be especially careful in their preparation of parents as to what will or might happen. Protracted deaths, unpleasant sights and sounds, and conflicting advice can all undermine parental confidence and leave families with a burden of guilt and distressing memories (McHaffie 2001). In an individual case, it is difficult to predict what will happen, but parents should be reassured that every effort will be made to ensure the baby will slip peacefully into death.

Ensuring freedom from distress is a sensitive issue that has attracted much debate. According to the law, any intervention with the purpose of procuring death is illegal, but medication given to alleviate suffering which has the side-effect of hastening death is permissible (Royal College of Paediatrics and Child Health & Ethics Advisory Committee 2004). Comfort may best be assured by the intravenous administration of opiates as necessary, with appropriate reassurance to the parents about the purpose of this analgesia.

Parental reactions to death vary but will usually include a mixture of anger, denial, numbness and great sadness. Having staff supporting them with whom they have already established a relationship allows them to laugh, or cry, share anecdotes, or express their fears and hostility, without fear of misunderstanding. Such members of staff may also express their own sorrow more freely, which the parents will appreciate. Although priority must always be given to the parents' needs and privacy, junior staff may learn best from watching the experts at work.

Asking for permission to carry out an autopsy is an extremely painful part of this process. With the adverse publicity of recent years, it has become even more sensitive. But where there are unanswered questions about this child or future obstetric risk, it may be the only method of obtaining answers (Brodie et al. 2002). A principal reason for resisting postmortem examination is the fear of mutilation, and parents may need help to acquire a balance of perspective which will enable them to make appropriate choices (McHaffie et al. 2001a). Assuring parents that their child will be handled in a dignified manner may help them make the correct choice for them.

Bereavement

Newly bereaved parents may find it difficult to leave behind the support of the neonatal team. The usual support systems such as friends and family that they now turn to are inadequate.

Parents appreciate staff attending the funeral, contacting them to check they are coping, and, if the parents wish, seeing them to talk about the baby. Commonly it is the nurse or nursing staff (with whom the parents have built a relationship) who provide these signs of caring, often in their own time. These gestures allow the parents to feel that they and their baby were valued and important to those caring for the infant.

Other sources of help, for both parents and staff, exist and should be suggested where appropriate. Self-help groups such as the Stillbirth and Neonatal Death Society or Compassionate Friends may offer solace to certain families. Other parents who have had similar experiences are trained to offer counselling via such organisations. But the difficulty parents sense in approaching strangers when they feel vulnerable and emotional should not be underestimated.

Medical follow-up

The consultant is the person who is key in the formal bereavement meeting, which takes place 4–6 weeks later (McHaffie et al. 2001b). The importance of this follow-up cannot be overemphasised. Parents value an unhurried session with the neonatologist and nurse most closely involved with their family. They have a great need to obtain information to help piece together what happened. It is also a forum to discuss the results of outstanding investigations, to discuss their implications and assess the parents' own future obstetric risks. The follow-up interview also provides an opportunity for staff to watch and listen to ensure that the couple are mutually supportive and experiencing a normal grieving process (McHaffie et al. 2001c). Such a meeting might ideally involve the appropriate consultant obstetrician and an observing paediatric trainee, but maintenance of intimacy is essential.

Other considerations

The general practitioner should monitor the mother's mood and somatic symptoms and offer advice on issues such as inhibiting breast milk production (Williams et al. 2008). Postpartum depression is common amongst mothers in the first few weeks to months following delivery. Having an ill newborn infant, prolonged neonatal intensive care and, of course, bereavement can compound feelings of guilt and inadequacy. Although postpartum psychosis is uncommon, the onset is earlier after birth than postpartum depression, and represents a psychiatric emergency (Pearlstein et al. 2009).

Conflict

In a well-managed neonatal unit, conflict between staff and families should be rare. Nevertheless, disputes do occasionally occur, and it is the duty of staff to identify the cause of any conflict and where possible anticipate and deflect it.

Anticipating trouble

Where emotions run high, there is a constant need for vigilance. Are the parents taking advice from well-meaning but ill-informed members of their family, and should these family members be interviewed too? Is there interparental conflict, and should this be

acknowledged and sidelined so that both parents, despite their differences, can contribute constructively to their child's care? Is the drug abuse of one or both partners interfering with their ability to make decisions? Should other professionals be brought in to facilitate better control of tempers or hostility so that discussions can be constructive once more?

Averting trouble

Almost always, conflict arises out of uncertainty, parental fatigue, and perceived or actual poor communication. Occasionally a schism can occur on the basis of ethnic or religious differences. Neonatal staff have stressful jobs. They too are only human and personal problems may make them vulnerable. It may be advisable on occasion to allocate another member of staff to a family, where interpersonal tension exists.

In a misguided attempt to cope with all situations, doctors sometimes forget they have allies. Colleagues and peers can be extremely helpful sources of advice. Conflict may diminish simply by bringing in another professional, perhaps of a different gender or ethnic background, perhaps from another city, able to look afresh at the clinical and emotional background out of which tension has emerged. Skilled interpreters may be invaluable in cases where language barriers are the root cause of conflict.

When tension stems from a breakdown of trust, written information may help. A detailed, factual account of the child's illness and prognosis may be taken by parents and discussed with trusted advisors, family and friends. The parents may be encouraged to write down all the questions troubling them. Each can then be explored in a follow-up interview. This exchange may also be documented, even recorded in audio format, giving the parents the opportunity to consider the situation calmly and in their own time.

Sometimes, parents are helped by having chosen advocates present. Young and inexperienced parents may benefit from their own parents sharing the discussions. A member of a minority religious group may draw strength from a minister or adviser who can explain the parents' stance from a more detached point of view. A sensitive clinician will be aware of special vulnerabilities and needs, and seek to circumvent conflict.

Managing abuse

Staff should be trained in containment of aggression. Occasionally, however, parents may be gratuitously or vindictively verbally abusive. They should be told politely but firmly that this is unacceptable. If the abuse is repeated, senior staff should give serious consideration to excluding the parent(s). If there is any threat of physical violence, security officers should be summoned immediately to have the offending party removed, in order to protect the babies, the staff and other visitors to the unit. The consultant will then meet with senior management, social workers, hospital security and the police, to develop a plan which will maximise the safety of all those involved, even if it means, in extreme cases, excluding the parents on a permanent basis from the unit.

Dealing with complaints

The consultant takes ultimate responsibility for the care of the baby and family: if a complaint is made, the consultant should be involved in addressing it. It is worth noting that if complaints are not addressed quickly, then they tend to multiply.

A first task is to establish the facts. Listening to the parents is the most important aspect of dealing with such a situation and every

effort should be made to adopt an unhurried and sympathetic approach. If the complaint is justified, then staff should be generous in their apology. 'I am sorry we made a mistake. I recognise you are angry. We will do everything to ensure that this does not happen to you or to any other family again.' If the complaint is not justified, then, having listened attentively to the criticisms, the consultant should express regret for the parents' distress but endeavour to give a reasonable and justifiable explanation for any misunderstanding. It may or may not be accepted, but simply being given a fair hearing may well go a long way to satisfying the parents.

Multiple complaints

Multiple complaints usually arise when an initial complaint has not been dealt with immediately. The family should be encouraged to write down each complaint and give the list to the staff beforehand. The consultant and colleagues can then explore the justification for each, obtain a full account of the events from those involved and agree upon a strategy which promises the best chance of regaining the family's confidence. In this situation, and especially where the complaints are of a serious nature, it is often helpful to have an independent chairperson to reconcile staff and family. Where this person is perceived to be autonomous and impartial, it can be easier to steer clear of personal attack, preserve a proper balance and sense of proportion and highlight areas of genuine concern.

Special situations

Some situations that are encountered in neonatal units deserve a special mention. Certain types of parents may need special nurturing.

Parents of the acutely collapsed baby

This is often the most demanding of crises. The parents have relaxed, and believe that their child is now out of danger. Suddenly there is an acute deterioration. 'It must be somebody's fault' is a very understandable reaction, but a painful one for dedicated staff to cope with. Immediate answers may not be available. The doctor in charge does not yet know whether the 4-day-old baby has developed an unexpected septicaemia or whether there is a congenital abnormality such as hypoplastic left heart syndrome that has manifested itself now that the ductus has closed. There is a rush to treat infection, and to obtain cardiology advice. The parents may be forgiven for thinking that the staff cannot even identify which organ is triggering the crisis. In such circumstances, honesty is the best policy. The clinician should be very candid but also emphasise the positive aspects of care. 'Your baby, Rosemary, is very ill. We have put her back on the ventilator. There are a number of possible reasons for her new illness and it's important we identify the cause of her problems accurately. At the moment we are treating her for infection. I've asked for a specialist, a cardiologist, to come urgently to the unit so that we can get the best advice available. I am taking responsibility for the team caring for your baby, and as soon as I have more answers I will come and discuss our plans with you.'

Parents of the baby with chronic disease

After the whirlwind of delivery, resuscitation, ventilation, replacement surfactant and the rollercoaster of the early days of life, it is very common for a baby to enter a stable phase where there is neither a perceived improvement nor deterioration. This stage can

be immensely frustrating for parents. Weeks go by and nothing seems to be happening. Some days the baby looks less good than others. The parents sleep poorly. The staff may also feel discouraged.

Ongoing concern for the parents and good communication are imperative. Parents should never be made to feel they are in the way or troublesome with their frequent questions. Rather, understanding their dilemma can be supportive. 'We know you're having trouble sleeping. Don't hesitate to ring any time in the night just for reassurance. We understand how worrying this stage can be.' Provided it does not encourage false hope, it can be supportive to identify some area of progress and lift the parents' spirits by offering them a different perspective. For example, parents of a child with bronchopulmonary dysplasia may feel discouraged by his ventilator dependency. By saying, 'Yes, your baby is still in 30% oxygen, but look at his excellent growth. With every day that passes, he is making new lung', you are acknowledging the legitimacy of their concerns but giving them encouraging news too.

Long weary days cocooned in a neonatal unit can be depressing. Dedicated parents may need to be given permission to resume a life outside the hospital. Encouraging them gradually to change their visiting patterns may help them to acquire a healthier perspective.

The absent parent

Parents may feel inadequate in the intensive care setting, and may express their fear by staying away. It is the staff's duty to maintain the highest possible standard but this is much harder to achieve without parental collaboration. Every effort should be made to address the cause of their reluctance, to gain their confidence, and, with patience, to draw them into the team. Strategies might include meeting the absent parent on neutral territory; suggesting they bring a supportive friend or relative in too; identifying a specific and positive role for them to play; and perhaps contacting the family's general practitioner or health visitor to obtain insight into the home situation.

The unsupported teenage mother

Even the most junior members of staff will find themselves caring for mothers and fathers who are several years younger than they are, but their attitude should never be patronising. Though chronologically younger, such parents may be surprisingly mature in experience, outlook and ability to cope. The unsupported teenage mother, however, represents a special challenge. Her abandonment may be temporary or permanent, but efforts should be made to establish the reasons for the schisms. Where the teenager's feelings will not be violated, separate interviews with her own mother may be indicated, in order to befriend her, and to persuade her that both mother and grandmother have an essential role in the child's care and future. If this is inappropriate or fails, then a close friend and/or a social worker should be brought in to support the teenage mother for the important decisions about her own and the baby's future. Patience, gentleness and understanding will all be needed.

The parent who takes control

This is a common situation. It occurs particularly where parents are intelligent, talented and challenging in their own professional lives. They are familiar with internet searches and soon become 'experts' in their baby's condition, treatment and prognosis. Such parents are used to being in control, and tend to channel their own

understandable anxieties into aggression, passive or overt. Staff should be sufficiently resilient to tolerate a mild degree of challenging behaviour, but as soon as it threatens to interfere with the quality of care of the infant, then it must be addressed.

The consultant should meet with staff and listen carefully to the facts, ensuring that they are neither exaggerated nor diminished. Together with another member of staff, he or she should then meet with the parents, and appeal to them to recognise the expertise and professionalism of the staff, and not allow their strong personalities to jeopardise the care the team want to provide for the family. Regaining control is essential to good relationships, and it is a mistake to allow parents to dictate which nurses and doctors they wish to take care of their baby. It may be necessary to set up regular meetings with such a couple to ensure that they are allowing the care of the child to progress unhindered by their anxieties.

The parent with special educational needs

In law, parents have responsibility for their child. Staff have an ethical duty to ensure that the care of the child is equally good no matter the educational attainments of the parents. On rare occasions, however, neonatologists are faced with parents whose level of literacy or understanding prevents them from properly grasping what is happening. Sometimes other members of the family may be able to act in loco parentis, and it is reassuring to have supportive grandparents who can make rational suggestions in the best interests of all concerned. Occasionally, it may be necessary to formalise this arrangement. If there is any doubt about who carries parental responsibility, or competence, the child-safeguarding team must be involved.

The parent who is a healthcare professional

It can be difficult to be the parent of an imperilled infant and also a healthcare professional. Roles and expectations between the two can become confused. Staff should encourage such a person to be a parent first, and expect no more of them than from any other articulate and intelligent mother or father. 'I am going to pretend that you are not a doctor. Indeed, with your permission, I would like to call you Mr Jones while your baby is in the unit', will often produce a smile of relief from the parent.

The mother with threatened extreme preterm labour

Ideally, counselling should involve both parents. The purpose is to provide information and to guide decision-making regarding the initiation or non-initiation of resuscitation. It is not possible to establish universal practice guidelines owing to the uniqueness of every situation. Gestational age should not be used as the sole

determinant of prognosis. Other relevant factors include gender, whether steroids have been administered antenatally, the presence of infection and whether there is more than one fetus (Batton 2009). It may be clear to the clinician that a fetus is too immature, and attempts at resuscitation are contraindicated. If however a good outcome is probable, resuscitation should be initiated irrespective of the parental view. The difficulty arises where it is not clear to the perinatal team whether the neonate might survive intact or with only mild deficits. Simply providing up-to-date outcome data and the intricate details about prolonged intensive care and expecting the parents to decide is unfair. Nevertheless the clinical team should be fully aware of the most relevant studies. Several meetings with the parents will be necessary to provide a clinical perspective effectively and empathetically. Parental choice must be taken into consideration but the professional team must always be primarily advocates for the child. The parents should be reassured that, in the event of non-initiation of resuscitation, the infant would receive compassionate care and that they themselves would be allowed to be involved in the dying process and its aftermath as much as they wish (Batton 2009).

Preserving your own health

Intensive care is demanding, and neonatal doctors and nurses work extremely hard for the families. We are groomed to succeed, and we feel guilty and inadequate when we do not. Every child's death and each physical deterioration can feel like failure. It is a mistake to cover up such feelings, and to look for solace in excess.

A healthy way to deal with perceived failure is to discuss troubling cases openly with peers. Reassurance may come from hearing that there was nothing further that could have been done, or from a shared sense of sorrow. Some teams favour routine debriefing after any stressful situation. These meetings, if skilfully handled, can be educational, and also beneficial for the corporate as well as individual morale. Maintaining a balance that includes an active life outside the neonatal unit is essential. Whether your interest is in the gym or theatre, climbing mountains or juggling flaming torches, it is essential for the carers to care for themselves if they are to be sufficiently restored to return to the neonatal unit and deal empathically with the next family.

Concluding thoughts

Neonatology combines the rigours of intensive care with the need to communicate openly and in detail with families. Counselling and support for parents cannot adequately be achieved in one meeting and take great patience and tact. Staff need to be articulate, thoughtful, sensitive and, above all, excellent at listening. It is hoped that this chapter has pointed the way, but excellence in practice is learned from peers, mentors and the families themselves.

Part 1: Ethics

John Wyatt

Introduction

All medical care is based on a primary moral commitment – a belief in the intrinsic value of human life. In this respect the practice of neonatology is no different from any other branch of medicine. It starts from a commitment to preserve and protect the life, health and well-being of newborns. It is this commitment that has motivated and driven the remarkable advances which neonatal medicine has achieved in the last 50 years. Yet these advances have created complex, troubling and controversial dilemmas for clinicians, for parents, for healthcare institutions and for the law courts.

The aim of this chapter is to provide a brief review of some of the moral and ethical issues raised by the practice of neonatology and provide references for further study.

Plurality of moral beliefs and ethical approaches

Modern societies reflect a plurality of moral beliefs, assumptions and 'world views' and ethical discussion is inevitably controversial and contested. There is little or no consensus amongst modern moral philosophers and ethical approaches range from consequentialist (in which the consequences of an action determine its morality), deontological or duty-based approaches, and virtue ethics, in which the character of the moral agent is central.

Despite the plurality of foundational beliefs and ethical approaches, it is frequently possible to reach broad consensus about whether particular clinical actions are morally right or wrong. We are all agreed that it is right to listen to parents, to treat them with respect and to seek their consent for giving invasive treatment. We are all agreed that it is wrong to inflict painful and unpleasant medical procedures on babies unless there is a realistic prospect that they can bring some benefit. As health professionals we have a responsibility to try to come to consensus on substantive ethical issues wherever possible, even if we disagree about the reasons behind our shared conclusions.

The value of life of the newborn

A very long-standing ethical debate concerns the fundamental value of the life of an individual newborn. The infanticide of unwanted, diseased or malformed newborns has been a common and socially approved practice in many cultures (Milner 2000). Infanticide and the exposure of unwanted newborns was a common practice in the classical Greek and Roman world and the oldest extant textbook on midwifery, written by the first-century Roman physician Soranus, has a chapter entitled, 'How to recognise the newborn that is worth rearing' (Soranus and Temkin 1991).

In the history of the west, a marked change in the attitude to newborn lives can be traced to the rise of Christianity. Jewish and Christian teaching emphasised the intrinsic value of life of all human beings, and linked into the *imago dei*, the image of God which each human life carried (Wyatt 2009). The idea of the sanctity of all human life sprang from the Judaeo-Christian ethical tradition but has been incorporated into national and international codes of law and human rights.

The UN Universal Declaration of Human Rights (United Nations 1948) and the UN Convention on the Rights of the Child (United

Nations 1989) both enshrine the intrinsic value of newborn life and the legal rights which every newborn holds. The latter upholds the 'inherent right to life' of every child from the moment of birth and lays a duty on member states to 'ensure to the maximum extent possible the survival and development of the child'.

It is clear that there is a stark difference in both national and international law between the legal rights of the newborn and those of the fetus. In most jurisdictions the fetus has no separate legal identity and cannot be the bearer of legal rights. But from the moment of birth, the newborn infant comes under the full protection of national and international legal conventions.

Recent philosophical challenges

The concept that a newborn life has an innate or intrinsic value equivalent to that of an older child or adult has recently come under sustained attack from a group of influential philosophers and ethicists. Although their views have gained little support amongst health and legal professionals, they are widely discussed in school and university courses on ethics, and it is important that neonatologists are aware of their existence.

Michael Tooley (Tooley 1972), Peter Singer (Singer 1995) and John Harris (Harris 1985) have argued that some form of self-awareness, the ability to see oneself as existing over time, is a necessary condition for having a right to life. Their views can be traced back to the thinking of the 17th-century English philosopher John Locke, who defined a person as 'a thinking intelligent being that has reason and reflection and can consider itself as itself, the same thinking thing, in different times and places' (Locke 1690). By this definition a newborn cannot be regarded as a 'person', and hence does not have an intrinsic right to life. Singer and others argue that the point at which human infants acquire a minimal sense of self-awareness is an empirical question which can be defined from psychological experiments but may not occur until the end of the first year of life. From this perspective a newborn infant should be regarded in the same way as the fetus as a 'potential person', a being whose life, although still of some significance, is intrinsically of less value than the life of an older child or adult.

Although logically defensible, this perspective has not gained significant currency amongst clinicians, and existing UK ethical guidelines from the General Medical Council (2007), British Medical Association (2007) and Royal College of Paediatrics and Child Health (2004) support the international consensus and argue that newborns should be treated with the same degree of respect, care and protection which we offer to all other patients. The guidance provided by the Nuffield Council on Bioethics Working Party (NCBWP) (2006) also supported the right of newborns and argued that 'a child of 6 days, months or years was worthy of equal consideration'.

Best interests

Doctors have a moral duty towards each individual patient to attempt to preserve life, restore health and prevent disease. Although the newborn's right to life is respected, all agree that there is no moral duty on doctors to provide every possible treatment in every possible clinical circumstance. Instead every action and treatment should be oriented towards the best interests of the individual child.

Although the phrase 'best interests' is intuitively attractive, it is notoriously vague and has been subjected to sustained legal and philosophical analysis. It is generally agreed that the determination of best interests involves the clinician in a difficult task of balancing and weighing a range of factors and opinions. General Medical Council guidance states that this should include the views of the parents and their cultural, religious or other beliefs and values, and the views of other healthcare professionals involved in providing care to the child. Preference should be given to treatment choices which least restrict the child's future options (General Medical Council 2007).

An assessment of best interests may also include, firstly, the current experience of the baby, especially the degree of pain and distress and the ability of the healthcare team to control this, and, secondly, the anticipated long-term outcome. The perspective, values and goals of the parents may be at variance with those of the health professionals and this may give rise to conflict and misunderstanding. In addition there may be disagreements and differing perspectives amongst the members of the health professional team, and it is important for these differences to be aired and, wherever possible, a consensus position reached. Where there is continuing disagreement and debate it is often helpful to request a second opinion from an experienced external clinician. The baby is reliant on the parents and the health professional team working in partnership, and every effort must be expended to develop and sustain a relationship of mutual understanding, respect and trust.

Both UK law and professional medical guidance seem to indicate that, where there is a conflict of interests, it is the child's interests which should, in principle, trump all others. Others have argued that the interests of the baby must not be allowed to take precedence over the interests of the parents and other siblings. The NCBWP recommended that those who make decisions in respect of a child should carefully consider the interests of all those who may be affected, especially other family members, old or young (Nuffield Council on Bioethics 2006). However, national and international statutes suggest that, in the event of a direct conflict of interests, the baby's best interests should carry greater weight than those of the parents or carers.

Balancing burdens and benefits

A traditional and helpful approach to ethical decision-making in medicine is the balancing of burdens and benefits, and this balance-sheet approach has often been adopted in cases which have come before the law courts. All treatments carry potential benefits to the patient but they also incur burdens and risks. The essence of ethical practice is to ensure that the potential benefits of all treatments offered should exceed their burdens. Any proposed treatment should be assessed within this framework, considering a range of factors – physical, emotional, social – and both short-term and long-term outcomes. The balance-sheet approach provides a helpful framework for ensuring that all aspects of a treatment decision are highlighted and incorporated into the decision-making process (General Medical Council 2010).

Withholding and withdrawing life-sustaining treatment

If life-sustaining treatment is futile because death is inevitable, or the treatment is excessively burdensome relative to the likely benefits, then there is no ethical duty to commence or continue treatment. It is generally agreed that there is no fundamental moral

difference between withholding life-sustaining treatment (such as resuscitation at birth) and withdrawing treatment which has already been commenced, although the psychological and emotional experience for staff and for parents may be different (British Medical Association 2007). Where there is genuine uncertainty about the likely benefit of invasive treatment, it may be appropriate to commence 'provisional' intensive support, whilst explaining to the parents that support will be withdrawn subsequently if it becomes apparent that there is no response to the treatment and that the prognosis is hopeless. On occasions parents may refuse to give consent to the withdrawal of life-sustaining treatment despite the unanimous conviction of the healthcare team that the treatment is futile or excessively burdensome. Parents need to be treated with respect, patience and empathy but, if no agreement can be reached, the primary ethical duty of the staff must be to protect the best interests of the baby, if necessary by recourse to legal proceedings.

Neonatal euthanasia

The mainstream approach to medical ethics has always drawn a sharp distinction between the withdrawal of life-sustaining treatment and an act of intentional killing or homicide. The distinction is not only one of an act of omission versus one of commission but is also based on the underlying intention of the act. When futile life-sustaining treatment is withdrawn, the intention is not to kill, but it is to limit the continuing harm and injury created by the treatment. If the infant continues to live following withdrawal of treatment, the medical goal is not to ensure that death occurs as soon as possible, but it is to provide palliative care, symptom relief, including the use of analgesic and sedative medication, and holistic care addressed to all the needs of the infant and family.

In 2005 a group of paediatricians from the Netherlands published a set of medical guidelines (known as the Groningen protocol) which supported the active ending of newborn life, using lethal drugs, under specified conditions (Verhagen and Sauer 2005). They suggested that intentional ending of life should be restricted to infants with 'a hopeless prognosis' who were likely to have a life 'full of suffering', but who were physiologically stable and not dependent on intensive support technology. The Groningen protocol has created considerable discussion and controversy but the active ending of newborn life has been explicitly rejected by professional and regulatory bodies in the UK and in most other national jurisdictions. Instead emphasis has been placed on the importance of skilled palliative care, effective symptom control and ensuring the active involvement and support of parents and other family members in end-of-life care (ACT 2009). There is a growing consensus that muscle relaxant agents have little or no role in palliative care, and their use may be positively unhelpful as they mask the clinical signs of pain and distress.

Quality of life and disability perspectives

Although it is often suggested that it is possible for health professionals and families to predict the future 'quality of life' of the critically ill newborn, there are major theoretical and practical problems with this concept. In particular it is often assumed by health professionals that a neurological or cognitive impairment translates automatically into a loss of well-being or life satisfaction. Yet empirical studies of health-related quality of life in ex-preterm survivors challenge this assumption (Saigal et al. 2006; Zwicker and Harris 2008).

Many disabled adults assert that many of the most significant factors which impair their life experiences are the social attitudes and political responses to their disability, rather than the biological impairment itself. In addition there is empirical evidence that health professionals and parents consistently undervalue the 'quality of life' of disabled adolescents and adults (Saigal and Tyson 2008). The unthinking use of 'quality of life' concepts in clinical decision-making is often unhelpful, and may be used as a cloak for prejudices and negative stereotypes about the lives of disabled people. Instead greater attention should be paid to recording and assessing the real-world subjective life experiences of babies, children and adults who have undergone neonatal intensive care.

unthinking use of published guidelines or clinical algorithms. Wherever possible detailed discussion with parents should be carried out before delivery and neonatologists should demonstrate attentive respect for the parents' beliefs and values, with the aim of achieving a consensus on appropriate action. If no agreement can be reached, clinicians have a moral and legal duty to act in an emergency in what they perceive to be the baby's best interests. As discussed above, preference should be given to treatment choices that least restrict the child's future options. This suggests that, in the presence of genuine uncertainty, resuscitation followed by a short period of provisional intensive care to allow detailed assessment and discussion would be appropriate.

Resuscitation of extreme preterm

Considerable attention had been paid to the ethical and practical clinical issues surrounding the resuscitation of extremely preterm infants at the limits of viability. The NCBWP guidelines use a week-by-week analysis depending on the gestational age of the infant at birth (Nuffield Council on Bioethics 2006). However there are a number of other clinical variables, such as birthweight, twinning, gender and exposure to antenatal steroids, which are of great importance in influencing the prospects of survival (National Institute of Child Health and Development 2008). Hence decisions about the appropriateness of resuscitation should be carefully individualised to the unique patient and family context rather than depend on the

Conclusion

Neonatology enshrines a primary moral commitment to the welfare and best interests of every newborn infant. Yet within the challenging context of a pluralistic society, it may be increasingly hard to find consensus on how this translates into practical decision-making in the intensive care unit. The perspective, values and goals of the parents may be at variance with those of the health professionals and this may give rise to conflict and misunderstanding. Yet the baby is reliant on the parents and the health professional team working in partnership, and every effort must be expended to develop and sustain a relationship of mutual understanding, respect and trust.

Part 2: The law

Bertie Leigh Janet M Rennie

Introduction

When neonatal medicine emerged as a distinct subspecialty, medical ethics was at a similar stage of infancy. Most decisions were assumed to be matters of 'common sense' and the law was widely regarded as another country where they did things differently. Today it is accepted that neonatologists have to take profound decisions of public importance which are likely to be subject to formal analysis in the courts. Decisions taken at the outset of a baby's life often have an impact decades later. The baby who is the subject of the decision may be unable to play any part in the discussion today, but as an adult will be able to ask pointed questions of the erstwhile clinician. In this chapter we will discuss some of these issues and give general advice as to how paediatricians should conduct themselves in those areas of their practice which are likely to bring them into contact with the law.

Clinicians and litigation

Maintaining professional standards

Neonatologists must maintain their own skills and the competence of their teams. Remaining 'in good standing' with the Royal College of Paediatrics and Child Health (RCPCH) involves participating in revalidation, appraisal and continuing professional development. Consultants must ensure that the neonatal unit has clear written guidelines and adequate staffing, that the facilities and equipment meet current standards (Ch. 2) and that outcomes are audited. Accurate, detailed contemporaneous notes must be kept: they are an intrinsic part of good care and the only part that is directly visible when the quality is called into question. Anticipation of possible litigation is not paranoia; it is good medicine to create clinical notes that record the progression of the patient in detail and make it explicit why particular decisions were taken, just as it is to obtain a second opinion in difficult cases. Intemperate remarks about colleagues and hasty judgements about areas that are not within your own competence are poor practice as well as being forensically unwise.

Handling adverse events, mistakes and complaints

Always be open and honest with the parents, but think calmly before you meet them after any adverse event. That a ventilator fails, or an intravenous infusion runs wild or a nurse makes a drug error is unfortunate, but it may not contribute to the baby's eventual problems. Do not make the mistake of thinking that because you are being candid about a complication you should be more hasty than you would be in other circumstances to give a gloomy prognosis. Think carefully about the way in which to treat the baby so as to minimise any damage and to break bad news so as to minimise parental distress.

If parents complain about your treatment or counselling, seek the advice and support of senior colleagues, including the clinical director and service manager early on, before matters get out of hand.

Appearing in court

Understanding the legal processes outlined in this chapter will help. Sometimes a decision is made not to defend a case even when the

staff involved feel that they did nothing wrong and that the adverse outcome was outside their control. There are all sorts of reasons why it is decided not to defend a case in court, and the decision does not necessarily imply that the criticism advanced by the claimant is correct. In this situation, give in gracefully and remember that giving evidence in court is not a pleasant experience for any doctor. However, if it is decided to defend the case, then be prepared to spend time and energy in preparation (reading all the notes and documents in the case) and in attending court.

In a civil court, remember that the judge is the most important person in the room. Address all your answers to him or her, not to the barrister who is questioning you. Tell the truth, in simple language, think before you start talking and speak very slowly: this gives the judge time to write down what you are saying and you time to think about your answer carefully. Do not be afraid of generating silence whilst you consider your answer. The pace of a courtroom seems very slow to those used to the frenetic activity of intensive care units. Do not engage the opposing barrister in banter, or let him needle you, or try to score a point at his expense – it is his home territory, not yours; his views are not in issue, but your objectivity is. Answer the question after due thought, preferably with a straight 'yes' or 'no'; but if you feel you are being forced to answer an inappropriately closed question then do not be afraid to say 'yes, but ...' with one concise, crisp sentence. Resist the temptation to embark on a mini-lecture. When you have finished your answer, stop. Do not fall into the temptation of embellishing or clarifying, simply because the cross-examiner waits and looks as if he expects you to do so.

Situations with a high risk of litigation in neonatology

General

Good notekeeping and clear protocols are vital, and it is important to keep copies of old protocols when they are updated because they establish the standard of care for that era. Never amend protocols by adding to them in manuscript so that it is impossible to tell when the old version was superseded: always redate and reissue the whole protocol. Do not 'save up' amendments or hesitate to change the protocol simply because the amendment involves only a few words. A protocol you can no longer defend in detail is a hazard to the unit and its patients. Always communicate the updated protocol to those who need to follow it and explain the reasons for the change. Cases are judged by the standards of the day, and in a rapidly advancing field like neonatal medicine it can be difficult to recall precisely when practice changed in your unit unless there is documentation.

The standards of care are those of a reasonably competent practitioner, and the courts do not expect that protocols will be changed to reflect every research finding. For a while, there was a fear that protocols would be used to drive litigation in cases where the clinical management had not followed a prescribed guideline. This is not a justification for the lack of a protocol, because in practice claimants usually succeed only when the standard of care is substandard by definitions that are common and beyond dispute. If the unit decides to deviate from a national (National Institute for Health and Clinical Excellence (NICE)) guideline the reasons for this must be clearly laid out.

Resuscitation

If a baby develops athetoid cerebral palsy as a result of damage to the deep grey matter after a short period of acute profound hypoxia in the immediate run-up to delivery, the quality and timeliness of the resuscitation will be under intense scrutiny. Minutes matter in this situation, and if the neonatal team arrive late, for whatever reason, the fact should be documented and the reason. Common problems are failure to intubate, incorrect endotracheal tube position and failure to use chest compression. It is not below a reasonable standard of care to intubate the oesophagus, but it is substandard care not to recognise it. It may not be below a reasonable standard of care for a junior doctor to be unable to intubate, but it will be if this doctor persists in the attempt too long, allowing the baby to desaturate, rather than using bag and mask and calling for help. It is substandard care to use a very small size of endotracheal tube in a term baby, or to insert it so far that it lies deep in the right main bronchus and leave it there.

A need for resuscitation does not equate to a diagnosis of 'birth asphyxia' and this cannot be stressed too often. Still less does it provide any basis for long-term prognostication. To act on the presumption that it does will not discharge a duty of candour but will cause needless and unwarranted distress. Use the term 'birth depression', for which there are a number of causes, including hypoxia-ischaemia during labour. Similarly, the term 'flat' is imprecise and means different things to different observers. We have seen this term applied to anything from stillborn babies through to babies who responded to blow-by oxygen after a few minutes. Similarly, 'shocked' should not be used to describe a baby unless there is genuine evidence of cardiovascular shock with hypotension and acidosis.

Obtain both cord blood pH results if possible and document the baby's early course very carefully with a narrative about the condition at birth and the response to resuscitation. Remember that babies who recover sufficiently quickly to remain with their mothers are sometimes at the end stage of a prolonged period of 'chronic partial' hypoxic ischaemia and develop seizures at 12–24 hours.

If resuscitation has to be abandoned make sure the decision is appropriate, be sure that the baby is not left alone and treat the body with dignity at all times. Never, ever leave a baby's body exposed and unattended on the resuscitaire and rush out of the labour ward. Initiating resuscitation in very immature babies generates a great deal of anxiety, but if stopping resuscitation appears to be the appropriate decision, supported by senior input, then fear of litigation should never inhibit clinical judgement.

Early neonatal encephalopathy and brain damage

Babies who seize in early neonatal life do not always have hypoxic-ischaemic encephalopathy, even if there was birth depression. However, there is a high risk of sequelae in this situation and the diagnosis should be pursued with vigour. Lumbar puncture and a search for infection are mandatory (Ch. 40.2). Investigations should include imaging, electroencephalogram (EEG) and metabolic screening. Do not prognosticate too early, but if it is appropriate to offer to withdraw care seek the support of a colleague, and warn the parents that the baby might not die.

The first duty of the neonatologist is to limit any further adverse effects by maintaining blood pressure, glucose levels and blood gases. Referral for therapeutic hypothermia should be considered where a local programme exists (Ch. 40.4).

Current litigation practice in the UK is dominated by claimants with cerebral palsy who ascribe their disability to hypoxic ischaemia

during labour, and a key plank of their causation argument is their ability to demonstrate early neonatal encephalopathy. The notes need to be careful, thorough, non-judgemental and include a daily description of the baby's neurological state. Avoid the temptation to record an absence of change without explaining what has not changed and make positive factual observations of the child's condition.

Investigation needs to be thorough and appropriate. This is not difficult (Ch. 40.1), but it is remarkable how often there is no pH, no head circumference, or no description of fontanelle tension, muscle tone or level of alertness in a baby who is being treated with several anticonvulsants and whose nursing notes suggest that she is totally obtunded. A Kleihauer test can be vitally important in establishing the diagnosis of fetomaternal haemorrhage. It is embarrassing, to say the least, if a diagnosis of congenital cytomegalovirus, CHARGE syndrome or an inborn error of metabolism is only established once legal proceedings are well underway.

There is no doubt that asphyxia can cause brain damage, but the majority of babies who suffer asphyxia at birth do not go on to develop brain damage, and 90% of cases of cerebral palsy are not attributable to birth asphyxia. Furthermore, sometimes the signs of fetal compromise in labour are associated with brain damage that has been sustained previously. This means that the association can be difficult to understand and is in part a diagnosis of exclusion. We suggest that the following list of features reflects the approach of most experts who advise the courts at the moment:

1. There must be evidence of significant fetal compromise if the fetal heart rate was being monitored at the time when it is suggested the damaging hypoxic ischaemia was sustained. Since the vast majority of children tolerate the stresses of labour without sustaining damage, there must be good evidence to pinpoint the insult to this time. Although electronic monitoring is not specific it is highly sensitive and it is unlikely that a child will suffer brain damage due to ischaemia at a time when the heart rate appears to be normal in rate and variation.
2. If it is suggested that profound damage was inflicted at the end of labour the neonate must exhibit clear evidence of this recent near-death experience. The Apgar score is not measured to predict outcome, but if the baby scores 2 for circulation at birth it is unlikely that the circulation has recently collapsed, and a 5-minute Apgar of 6 or above is not consistent with a recent acute profound hypoxic-ischaemic injury.
3. The human organism will metabolise anaerobically in response to hypoxic ischaemia. Thus a baby who does not have an acidosis is highly unlikely to have experienced significant hypoxic ischaemia recently. If the cord blood was sampled the diagnosis of acute profound hypoxic ischaemia in the immediate run-up to delivery becomes difficult to establish if the arterial pH is above 7.0 and the base deficit less than 12, and can usually be excluded if the pH is above 7.1 and the base deficit less than 8. It is always important to consider the arterial as well as the venous cord blood and this is particularly important in cases of possible cord occlusion.
4. It is unlikely that brain damage has been sustained without there being signs of temporary damage to at least one other body system, although whether this has been recorded may be a function of how ill the baby was perceived as being at the time.
5. The baby born after 34 weeks must have exhibited severe or moderate neonatal encephalopathy (Ch. 40.4), because this is the stage in the evolution of the disease process in which

permanent damage is sustained. Increasingly, this diagnosis is supported by evidence of an abnormal EEG or aEEG.

6. The child must have a disability capable of being attributed to birth asphyxia. Traditional thinking held that spastic and athetoid cerebral palsy were the only disabilities in this category, but it is now appreciated that learning difficulties can be caused by perinatal hypoxic ischaemia, although a motor disability is usually present as well.
7. Other more probable diagnoses must be excluded. This necessarily involves a careful and detailed investigation by a wide range of modern modalities, including biochemical tests and magnetic resonance imaging (MRI). Particularly important in this category is the diagnosis of stroke.

In many of the cases we are asked to assess, the fact that the baby has sustained perinatal hypoxic-ischaemic damage is not in dispute so much as the precise timing of the insult. Where the mother reports a sudden loss of fetal movements a day or two before delivery this may take on a more sinister significance in the light of subsequent events. In all these cases early cerebral imaging, EEG or Doppler studies may be decisive. In future, diffusion-weighted MRI or MR spectroscopy may shed more light on the precise timing of events.

Preterm brain injury

Preterm brain injury is usually caused by a complex sequence of interacting factors, which makes establishing causation even more difficult than at term. Further, much preterm brain injury is not preventable in the present state of the art, however meticulous the care. However, if the prematurity was the result of an inappropriate early delivery (because of miscalculated dates, for example) the child may mount a claim for iatrogenic prematurity. Some disabled ex-preterm children born after the mid- to late 1990s have mounted successful claims based on the association of hypocarbia with periventricular leukomalacia. The same is true for those whose mothers were not offered antenatal steroids (when appropriate) after about 1994, when the first Royal College of Obstetricians and Gynaecologists (RCOG) guidelines were issued.

Adverse outcome after preterm birth is an area where neonatologists need all their skills in communicating with parents as well as treating their patients. The parents of a disabled child understandably seek a reason, and something to blame. If they are kept in touch with their baby's care and given an accurate prognosis and an explanation of any interacting causes as early as possible, they are less likely to ascribe the whole problem to the brief power cut on day 6, the disconnected ventilator tubing on day 33 or the possible misplaced nasogastric tube on day 40. Early and full explanations can avoid a long-drawn-out period of attrition which often ends in disappointment for all concerned. In our experience, it is very rare to go through a set of notes documenting a neonatal intensive care unit (NICU) stay of several months and find that there were absolutely no problems or errors at all, but it is rarely the case that any deficiency in care can be identified as the cause of an adverse outcome in a very preterm baby. As many studies have shown, there are simply too many hurdles for such babies to surmount for it to be clear which inflicted the lesion which will later prove disastrous.

Jaundice (Ch. 29.1)

Kernicterus is often a preventable disease, and, although it almost vanished from UK neonatal practice, it has now returned with a vengeance. The National Patient Safety Agency has made kernicterus

a 'never event' in the UK. Midwives and others concerned with newborn care need to be taught that neonatal jaundice can be an emergency. Early discharge policies and the welcome move towards exclusive breastfeeding have produced a new population of vulnerable babies. There is only one way the bilirubin is going in the first few days of life, and that is up. New NICE guidelines (www.nice.org.uk) became available in 2010 regarding the management of neonatal jaundice, including advice on when to measure the bilirubin and when to start and stop phototherapy (Ch. 29.1).

Evidence shows that the following are especially high-risk groups:

- near-term babies (35–37 weeks)
- babies whose mothers exclusively breastfeed
- babies whose siblings required treatment for neonatal jaundice (often a proxy for haemolytic disease)
- preterm babies with acidosis, and/or low albumin levels, or an 'open' blood-brain barrier because of germinal matrix and intraventricular haemorrhage or sepsis, who can develop kernicterus at low levels of bilirubin.

Effective intervention in all such groups requires anticipation as well as reaction.

Example Baby W was born normally at 07.26 on a Friday after a quick and easy labour. He weighed 3.68 kg with a head circumference of 35.5 cm. The baby check was carried out in the hospital during the morning by the family general practitioner (GP) who was providing care, and mother and baby went home soon afterwards. It was the mother's second child. The father was known to suffer from spherocytosis and during the pregnancy he was admitted to the same hospital with a haemolytic crisis.

On Saturday the community midwife visited at home and noted that W was jaundiced. She advised putting him outside in his pram in the 'sunlight'. By Sunday W was more markedly jaundiced and he was feeding less well; again sunlight was advised and the midwife said that a bilirubin estimation would be performed the following day.

On Monday W was irritable and arching his back, and would not feed. His mother took him to the GP, who arranged admission to the hospital, where his bilirubin was found to be 636 $\mu\text{mol/l}$. An exchange transfusion was done but was too late to prevent kernicterus, which was apparent on the late MRI. W is disabled by choreoathetoid cerebral palsy, upgaze palsy and deafness.

Hypoglycaemia

This is an area in which many claims are unsuccessful. Most experts consider that as a rule only prolonged periods of symptomatic hypoglycaemia are damaging, and there is now a typical (not pathognomonic) MR pattern described (Traill et al. 1998; Kinnala et al. 1999; Murakami et al. 1999), which has recently been extended (Burns et al. 2008) (Fig. 6.1). There can be no complacency about the management of hypoglycaemia, and appropriate protocols for screening high-risk groups must be in place and audited (Ch. 34.1). Transitional care areas are high-risk areas for this reason, and need to be recognised as such. Symptomatic hypoglycaemia is an emergency and intravenous treatment is mandatory. It is unusual for a term baby of normal weight whose mother is not diabetic to present with symptomatic hypoglycaemia, and there should be a high index of suspicion that the underlying diagnosis is hyperinsulinaemia right from the start in this situation, with the appropriate level of investigation and intervention, with early recourse to expert help.

Like hyperbilirubinaemia, it is now known that the normal healthy breastfed baby is not immune from hypoglycaemic damage

Fig. 6.1 Magnetic resonance imaging in a case of probable hypoglycaemic brain damage.

due to breast milk insufficiency, although the problem is rare. Monitoring the adequacy of breastfeeding is difficult, but must be routine midwifery practice and guidelines regarding the use of supplementary feeds need to be worked out between professionals. Babies who are small for dates or whose mothers have diabetes must have glucose screening using an appropriate method and with reasonable frequency (Table 34.3).

Retinopathy of prematurity

Children who are blinded from retinopathy of prematurity often litigate, not usually for poor management of their oxygen therapy but because the screening policy (Ch. 33) has failed them. This happens in two ways: either the recommended screen does not take place in the critical window of opportunity for treatment, or the screen takes place but the diagnosis is missed. There are clear UK (and international) guidelines that must be followed, and if a planned screening examination cannot take place at the scheduled time (for example, the baby may be too ill to tolerate the handling or even the dilating drops) the reasons should be carefully documented. The same is true if surgery has to be postponed.

Deafness

Most deafness is of genetic origin, and a careful family history and appropriate genetic testing are important. Claimants who attribute their hearing loss to gentamicin toxicity or hypoxic ischaemia occasionally succeed in proving their case. The impact of the discovery that a particular mutation enhances individual vulnerability to gentamicin toxicity has not yet been determined.

Infectious disease

Neonatal group B streptococcal disease commonly leads to litigation and deviations will be harder to defend now that there are

guidelines endorsed by the RCOG and RCPCH supporting a strategy for antenatal prophylaxis based on risk factors. Neonatologists need to work with their obstetric colleagues to devise and implement local guidelines and to think carefully about what should be done, for example, if a baby who should have been exposed to intrapartum prophylaxis is born before her mother receives it.

Neonatal meningitis is hazardous for doctors as well as for babies. Although the prognosis of established disease is poor, we see cases in which there has been an alleged delay in investigation or treatment, of inadequate dosing, inappropriate antibiotic choice or short duration of treatment. Clinicians must be aware that neonatal meningitis carries a high risk of adverse sequelae and take care to optimise antibiotic and supportive treatment, investigate fully and refer on when appropriate. Increasingly, when a disease has had an adverse outcome, the fact that this was predictable will not of itself prevent those concerned on the patient's behalf from scrutinising the records in retrospect to see whether the management was in fact optimal.

'Missed' abnormalities at the neonatal examination

It is difficult for parents to understand that no one was to blame when their baby, who was checked over and passed fit, collapses with coarctation of the aorta and requires major surgery, or develops amblyopia from a cataract, or a limp from developmental dysplasia of the hip. Yet none of these conditions is reliably detected by the routine neonatal examination (Ch. 14). Biochemical screening is reliable, but there are sometimes failures in communication which result in a hypothyroid baby starting treatment late. The introduction of screening for medium-chain acyl dehydrogenase deficiency is welcome, but serves to increase the need for adequate back-up to ensure that affected babies receive appropriate and timely expert advice.

Vitamin K-deficiency bleeding

There is still no agreed UK standard regarding the dose, route or frequency of vitamin K prophylaxis for vitamin K-deficiency bleeding. Parents are offered a choice in many hospitals. Parents who refuse vitamin K for their baby altogether should have their refusal documented. However, sick babies who are admitted to neonatal units should have intramuscular vitamin K. In this instance it does not matter what the mother said before the baby became ill, because by that stage vitamin K is a medically indicated treatment. It is inappropriate to wait for 7 hours for 'consent' in a baby of 28 weeks whose mother required an appendicectomy and who herself was admitted to the intensive care unit ventilated. If that baby develops intraventricular haemorrhage he may allege that the delay in vitamin K contributed to the problem. Any baby can become sick, and if he received oral vitamin K after birth (or no vitamin K) he should be given a further intramuscular dose, especially if surgery is required.

Scarring and iatrogenic problems (Ch. 44)

The scars of neonatal intensive care are not usually disabling, but on occasion extravasation injury can cause tethering around a joint which inhibits movement or causes disfiguring scars. This may be unavoidable, but constant vigilance is required to avoid inflicting scars which will grow with the baby.

Since the Department of Health warned that there is an increased risk of cardiac tamponade when Silastic long lines are sited in the right atrium, neonatologists should only continue to site lines in

the heart when there is no alternative. A long line which inadvertently lies in the left ascending lumbar vein can cause permanent paraplegia, via direct extravasation into the subarachnoid space or by causing a vasculitic response with venous congestion in the small veins of the epidural plexus.

Relations with parents

The therapeutic alliance with parents

Wherever possible the neonatologist and the parent should form a relationship based on profound mutual trust (Ch. 5) and close cooperation. The quality of care on the NICU is enhanced if the parent who is to look after the child exclusively in the near future is fully involved in the decisions about the treatment of the child and in the delivery of that treatment in so far as may be practical.

Maintaining this relationship requires time and effort, and time can be difficult to find in the hurly-burly of a busy intensive care unit. Continuity can help, and the 'attending' system operated by most neonatal teams may be modified to allow parents to form a relationship with one consultant.

Many parents find it advantageous to have contact with several consultants, who might put things in different ways, and sharing the emotionally draining load of counselling is valuable if senior staff are to avoid 'burnout'. If parents are to derive maximum benefit from this multiplicity of view, colleagues must have confidence in each other to communicate in their own way, not to undermine each other and to convey the same message. This demands that the doctors involved maintain a high degree of communication so that the parents are not confronted with conflicting information and inconsistent advice. Practitioners must be aware of what each other has said and such extensive sharing of information demands detailed records and regular discussions. We have found that including this as an item on the agenda at the weekly meeting between consultants and senior nurses has been invaluable in achieving better information sharing.

Informed consent

It is well established in English law that an adult patient with capacity to take a decision can refuse treatment for good reason, bad reason or no reason at all. The law respects the patient's autonomy and the doctor who operates or treats such a patient without that patient's consent is guilty of an assault. Assault may give rise to a liability to compensate without proof of damage in the civil courts, to a prosecution in the criminal courts and may be punished by the General Medical Council as professional misconduct. The same legal principles apply to babies save that the operative consent has to be given by someone with parental responsibility. Parents have the right to decide what treatment their children should receive and doctors should act in partnership with parents wherever possible. However, parental rights are not beyond the review or control of the court: they derive from the parental duty to look after the child and they exist for the benefit of the child rather than the parent. Indeed, it has been suggested that, when a doctor operated on a child with the consent of a parent but the operation was manifestly not in the best interests of the child, the doctor would commit an act of trespass as well as being liable to an action brought by, or on behalf of, the child in negligence.

Which procedures require written consent?

A consent will be equally valid whether it is given orally or by conduct, as where someone sticks out an arm to receive an

injection. Similarly it does not need to be recorded in writing to provide a defence to a claim of assault. The reason why the consent to more serious interventions is recorded in writing is to provide evidence, not only that the patient consented but also that the doctor complied with the obligation to counsel the patient. When seeking consent a doctor incurs a duty to explain what is involved in the procedure, and to advise of the risks and benefits so as to put the parent in a position to take a sensible decision. In order to demonstrate that the parents' rights were respected it is increasingly necessary to record that the proper explanations were given and formalities were complied with. Just as consent to an injection is incomplete without knowing what is in the needle, there is an increasing need to record in detail the explanation that was given. In the past, written consent was only sought for major procedures such as surgery or exchange transfusion. The British Association of Perinatal Medicine (www.bapm.org) has produced a useful list of procedures for which it is proposed that consent is obtained.

Who is able to give consent?

Single mothers

Either parent has the right to consent to the treatment, providing the parents are married or the father has acquired parental responsibility. If the doctor is on notice that the parents disagree it will be wise either to try to obtain the agreement of the second parent or to suggest that they should go to court to have their differences resolved, but as the court stated in one leading case:

If the parents disagree, one consenting and the other refusing, the doctor will be presented with a professional and ethical dilemma but not with a legal problem because, if he has the consent of one authorised person, the treatment will not without more constitute a trespass or criminal assault.

There are a few exceptions to this general rule: ritual circumcision should only be done with the agreement of both parents (*Re U*). There are procedures on children which should only be done with the prior authority of a court order even where both parents consent. These include non-therapeutic sterilisation and the donation of regenerative tissue such as bone marrow, or of an organ such as a kidney. Although it has not happened yet, it seems likely that progress with stem cells will lead to neonatologists being involved in such issues in the future. The court will seek to balance the degree of risk to the baby against the likely benefit to the family of which that baby is a member.

Very young mothers

Increasingly common on the NICU is the single mother aged under 15 years. Often she will be 'Gillick-competent' – able to understand information given to her about her baby and make decisions for herself – but sometimes children are born to mothers so immature that the doctors would be reluctant to accept their consent to treatment of themselves. Nevertheless, only the mother can give a lawful consent to treatment of her child. Often the doctors will be able to involve the grandparents or the biological father in the treatment of the baby, for the same reason that it is good practice to involve the parents of the Gillick-competent child in her own treatment. However, it may well be that in such circumstances the hospital will feel that the Social Services department should be involved because the baby, if not the young mother, is in need of support. Social Services are the lead agency for children in need and may decide to make an application to the court.

Psychiatrically ill mothers

Women with long-standing psychoses sometimes relapse when pregnant or during the puerperium, and women without any previous psychiatric morbidity can become seriously ill for the first time after giving birth. If they are single, this can present major problems for those caring for their baby. The starting point in this situation is with the mother's consultant psychiatrist, in order to establish a perception of her ability to process information and take decisions. On occasion, we have managed withdrawal of care in this situation by involving a team of psychiatrists, social workers, family members and other therapists with a team from the neonatal unit. Where the mother is too ill to give informed consent we have had to involve Social Services or the courts: even here it is good practice to involve the mother as much as possible.

Use of interpreters

Recent National Health Service (NHS) guidelines have made it clear that the long-established practice of relying on family members (particularly children) as interpreters is no longer acceptable. The reason for this is that the mother or father of the interpreter may have information which he or she wishes to convey, but which he or she does not want the rest of the family to know – for example, a diagnosis of human immunodeficiency virus. Further, there is no way of knowing that family members are translating complex medical information accurately. If parents do not speak English well enough to understand the information they need to give consent, a suitable interpreter must be obtained. There is a scarcity of interpreters in some languages and the cost of face-to-face interpreters is a considerable financial burden for many trusts; telephone interpreters can be used for some consultations. Provision of interpreters cannot overcome the problems associated with the everyday informal contact which is essential to effective partnership between the parents and the rest of the team on the neonatal unit.

Documentation of counselling, and which risks to mention

Neonatologists are under an obligation to ensure that parents understand the nature and purpose of the procedure for which they are seeking consent. This includes making sure that they understand the expected consequences and the risks involved in the procedure. It is less often spelled out that the doctor has an obligation to make clear the consequences and risks of not undergoing the procedure. A doctor who negligently deters a patient or parent from consenting to a procedure by giving an exaggerated view of the hazards will incur a potential liability if the parents decide not to allow their baby to undergo the procedure and the baby meets with disaster as a result.

As to what risks should be mentioned, it is sometimes said that there is a 1% rule – all risks with an incidence of 1% should be mentioned. That may be a useful starting point but it certainly does not describe the risks which need to be mentioned. A much more remote risk of death or disability will usually have to be discussed. The doctor should also take account of how much real choice there is, how much time there is to take the decision and how much information the parents wish to have.

Refusal of treatment

There are some cases where the parents refuse treatment which the doctor believes is essential in the interests of the child. In those cases the courts can make orders authorising treatment and the

doctor must not hesitate to take whatever step is clearly necessary in the interests of the patient. However it is much better to carry the parents with you if possible and conflict resolution can often be achieved by the use of mediation services or family advocates. Often the most effective first step is to offer to obtain a second opinion, either from a colleague in the same hospital or from another institution: it is important to stress that the opinion needs to come from a respected neonatal doctor or a subspecialist in the management of the condition in question. Both parents and doctors can benefit from such advice and most colleagues are willing to give such advice to NHS patients without making a charge.

The court has various legal bases on which it can make an order that treatment will be lawful. For example, it can simply determine a single issue as to what would be in the child's interest under section 8 of the Children's Act 1989, or it can make the child a ward of court so that all important steps in the child's life have to be sanctioned by the court. Alternatively, under what is called the 'inherent jurisdiction', it can make whatever orders seem appropriate. As Lord Woolf put it, particularly in regard to cases involving children, the last thing the court should be concerned about is whether the right procedure has been used (*e R (A Minor) (Blood Transfusion)* [1993] 2 FLR 757). The important thing is to ensure that the best interests of the child are identified.

The fact that the parents and doctors disagree to such an extent that the court has to resolve the difference of opinion increases the importance of maintaining the doctor-parent relationship. Disagreement, where it is moderately expressed with mutual understanding and respect, does not necessarily entail enmity. These cases arise when both doctor and parent want what is best for the child in a situation where neither can foresee the future or know how the child would wish them to act. Having submitted their shared dilemma to the court, the parents just as much as the doctors may be prepared to play their full role in the baby's care, whatever the decision may be. It is the doctor's professional duty to facilitate that process.

Jehovah's Witness parents

An adult Jehovah's Witness is free to refuse a blood transfusion and a doctor who forces an unwilling Jehovah's Witness to accept the treatment will be guilty of an assault. However, it is important to note that not all Jehovah's Witnesses share the same views: some will accept treatment with some blood products (such as fresh frozen plasma) and others do choose to accept blood when the alternative is death. It is vital to ascertain the wishes of the individual patient and to help the patient to stand up to pressure from co-religionists or other family members. Useful guidance on this topic is available from the Association of Anaesthetists' website (www.aagbi.org).

As with any parent, Jehovah's Witnesses have the right to take decisions as to what treatment their child should receive. However, if it is plain that the blood needs to be given, the court will make an order that it is lawful to do so, even when both parents object. If the baby's condition is so precarious that death or serious injury is likely to follow unless blood products are immediately given, again it will be lawful to do so even though there is no time to get a court order. In *Re R (A Minor)* the court had to deal with a child with B-cell lymphoblastic leukaemia who was given blood products on admission as an emergency measure without the parents' consent, and the court subsequently approved the administration of blood products in the future. However, it is important to note that the court decided that the medical consultant should not be given a blanket authority to carry out such treatment without further reference to the parents, and that the parents should still be

involved as far as possible in the care of their daughter and able to draw attention to treatments alternative to the use of blood products.

In our experience the best approach in this situation is first to think hard about the indication for blood products – is there an alternative? What is standard and safe practice? Juniors must discuss the situation with a consultant, and consultants may wish to seek the support of another colleague. The reason for the transfusion and the urgency should be carefully explained to the parent (or parents), and an offer made to talk to any religious advisers the family may choose. Many hospitals have panels of on-call volunteer Jehovah's Witness ministers who are prepared to come and help. They can provide invaluable assistance in the counselling and mediation process, and in our experience have largely obviated the need for court applications in recent years. Only if such a reasoned approach fails should a court order be sought, and then only if time allows. Obtaining a court order involves the hospital's solicitors and social workers, but when required a court order can usually be obtained within hours.

Emergency situations

In an acute emergency or when the parents refuse to consent to treatment that is immediately necessary for the preservation of the life or long-term health of the child, the doctor is empowered to act. The precise basis of this agency of necessity (as it is sometimes called) is unclear, but the doctor's duty is towards the child; if it is clear that the child is about to die because some treatment is immediately necessary the doctor should act in the child's interest even if the parents forbid administration of the treatment.

Thus when a paediatrician is called to resuscitate a newborn baby with an Apgar score that indicates that any delay may result in brain damage, if not death, the doctor is not required to obtain the consent of the parents before addressing the immediate needs of the patient.

There may be cases where the parents refuse to consent to treatment that is immediately necessary to preserve the well-being of the baby, when the situation is so acute that there is no opportunity to enlist the authority of the court. Then the doctor must act in the best interests of the patient. However, it is helpful to know that the authority of the High Court can be enlisted in a telephone hearing surprisingly quickly. Once the acute emergency has passed, the situation should be explained to the parents. If the parents cannot be reconciled to the decision that has been taken and there is any significant likelihood of a recurrence or the treatment needs to be continued, then the court should be approached as soon as possible.

Discontinuation of futile treatment

A decision to withdraw life-sustaining treatment precedes about 30% of deaths in a NICU, and an understanding of the process is an essential part of every consultant neonatologist's training. The best source of guidance remains the RCPCH Framework for Practice of September 1997, updated in 2004, and this framework has now been cited with approval by the judiciary on several occasions (www.rcpch.ac.uk). We have reviewed some of the key judgments in this area (Rennie and Leigh 2008).

The framework identifies five situations in which the decision will be considered:

1. the brain-dead child
2. the permanent vegetative state

3. the no-chance situation, when disease is so severe that life-sustaining treatment simply delays death without significant alleviation of suffering, rendering medical treatment inappropriate
4. the no-purpose situation, when there may be survival with treatment but the degree of impairment will be so great that it is unreasonable to expect the patient to bear it
5. the unbearable situation, when in the face of progressive or irreversible illness, the child or family feels that further treatment is more than can be borne.

The detailed guidance given by the RCPCH should be followed. It is vital here to stress the following:

1. The withdrawal or withholding of treatment does not imply that a baby will receive no care. The baby remains your patient and you must do your best for her just as much whilst she is dying.
2. It must be noted that there is no significant difference between withholding and withdrawing care as far as the courts are concerned. It is unlawful to take any positive act which will result directly in a person's death, but the withdrawal of treatment in hopeless circumstances is not a positive act.
3. The decision should be discussed widely within the clinical team and varying views recorded. If there is substantial dissent or if the parents do not agree, a sensible first course may well be to obtain a second opinion from another clinician with experience of the clinical problem. In the last resort the courts are there to give guidance but, as the RCPCH Framework makes clear, in most cases it will be possible to avoid an application to the court.

Many neonatologists believe that, on occasion, to continue intensive care may be inappropriate and inhumane. Many would take the same view about 'show code' or sham resuscitation, done for the benefit of the parents when most of those in the room see the situation as hopeless (Paris et al. 2010), although not all intensivists view this the same way (Truog 2010). Managing this kind of case is challenging and requires a degree of consensus in the treating team. Kant's view that 'it is immoral to use one human being as a means rather than as an end in itself' may imply that inflicting the burden of intensive care on a baby when there is no prospect of success cannot be justified. The problem lies in defining 'no prospect', or 'no chance', because there may be differences of opinion amongst the treating team, or between them and outside experts. When there is unanimity of opinion, the matter can usually be resolved either with or without the intervention of the court.

Unrealistic expectations regarding treatment

Reports of 'miracle survivors', with titles such as 'Neonatal viability: pushing the envelope' (Muraskas et al. 1998), have raised parental expectations to the level that a good outcome is assumed for every baby born after 23 weeks' gestation. Parents often request that 'everything be done' for their babies, however complex the problem and however overwhelmingly the odds are stacked against success, and they sometimes have difficulty in coming to terms with the disappointment of these hopes.

The most extreme example is probably that of baby K, an anencephalic, whose mother insisted on full intensive care support for over 2 years. Neonatologists need to be careful not to add to these unrealistic expectations, or to use the word 'miracle' themselves; the argument used by the doctor who initially resuscitated baby K was that the mother 'needed more time' to adjust to the fact that she could not live. Additional time did not lead to any more acceptance,

and baby K's mother continued to believe that a miracle would happen. As Paris et al. (2000) put it: 'if parents are expecting a miracle they have come to the wrong place'.

At the other end of the spectrum are the parents who want a guarantee of success before agreeing to treatment for their child (Paris and Bell 1993). Things have moved on considerably since the 1963 Johns Hopkins case of a baby with Down syndrome and duodenal atresia who was 'allowed' to die over an 11-day period, and newborn babies are now recognised to have rights. Few would accede to a parental request for no treatment in this situation today, but the judgement regarding what is a 'reasonable' chance of success does vary between professionals and these differences need to be recognised.

There are now several documented cases in which the courts have been involved in this situation, in both the USA and the UK. The implication of the decision of the European Court in the case of Glass is that doctors should be much more willing to enlist the guidance of the courts at an early stage. We think that in future the courts are likely to be involved in a wider range of these problems than hitherto and that there can be advantages in hospital and parents going to the courts together for guidance at a time when attitudes are less entrenched. Just as we suggested when parents refuse to consent to treatment (see above), the authority of the court can be used to resolve a shared uncertainty as opposed to an established antagonism. Whatever the decision, it may be easier to implement if both sides have been through this process.

Negligence

Medical negligence consists of a breach of duty of care which causes damage. Claims in the UK are heard in civil (not criminal) courts by a judge sitting alone who has to find that it is more likely than not that there was a breach of duty and that the claimant's disability was caused by the mistake in question.

Breach of duty

The doctor will be in breach of her duty of care only if she fails to provide a reasonable standard of care. Lord Scarman described the standard which must be achieved by quoting a Scottish judge who had said (*Maynard v W Midlands* 1985):

In the realm of diagnosis and treatment there is ample scope for genuine difference of opinion and one man clearly is not negligent merely because his conclusion differs from that of other professional men ... The true test for establishing negligence in diagnosis or treatment on the part of a doctor is whether he has been guilty of such failure as no doctor of ordinary skill would be guilty of acting with ordinary care.

The principle that the law will respect treatment which accords with a respectable school of thought is known as the 'Bolam test' (*Bolam v Friern* 1957). It applies whether the doctor is reaching a diagnosis (*Maynard v W Midlands* 1985), giving warning of the hazards of treatment (*Sidaway v Bethlem and Maudsley* 1985) or performing a surgical procedure (*Whitehouse v Jordan* 1981). The court reserves the right to reject an opinion which it believes does not stand up to logical analysis (*Bolitho v City & Hackney* 1992). In the case of care delivered by a team, the law does not require the most junior trainee to have the skills of the consultant. However, it does require the trainee to be competent to perform the tasks allocated to her (*Wilsher v Essex Health Authority* 1986).

Where a defendant is in breach of her duty of care, the claimant will only be entitled to be compensated for damage caused by that breach of duty. This can cause additional complications; for

example, when a senior registrar at a London teaching hospital failed to respond to her bleep to attend a child with croup, the evidence was that it would have made no difference to the exegesis if she had attended, unless she had decided to intubate the child as a precaution against a subsequent attack. The House of Lords held that causation could not be proved if a reasonable senior registrar in her position would have decided not to intubate (*Bolitho v City & Hackney* 1992). If the defendant is guilty of an act of negligence then the court will require that the claimant is put in the position in which he or she would have been if there had been no negligence, insofar as money can achieve this.

Standards of care

The law holds that doctors are to be judged by the state of their art at the time of treatment. They will not be negligent if they fail to anticipate a hazard which was unknown at the time (*Roe v Minister of Health* 1954). It is often said that the *Bolam* test provides a protection for the slower members of the profession, who cannot keep up with the state of their art – provided that they do not fall too far behind. However as medicine becomes more systematised at the hands of NICE and the evidence base of the Cochrane Centre expands, it is increasingly difficult to defend suboptimal care when damage has been caused. Where a case presents a powerful emotional charge it is hard to defend any adverse outcome that optimal care would hope to avoid. We were recently both involved in a case where a 5-month-old baby suffered a cardiac arrest as a result of a pneumothorax as she was being moved from the table after open-heart surgery. The facts were 27 years old, the witnesses all dead or otherwise unavailable and the records vestigial and mostly lost, yet the court was prepared to infer a breach of duty from the fact that the pneumothorax was not diagnosed before it caused an arrest (*Mugweni v NHS London* 2011).

This was not atypical of cases that come to court after many years have elapsed. Even when the notes still exist, they are vestigial by modern standards. Investigations appear to be sporadic and haphazard. The witnesses are worse: those who survive can rarely remember anything of the facts in issue, even though they may be debating the few hours in which it seems the claimant met with the catastrophe which has blighted her existence. Under the rigours of cross-examination, those involved may be hard-pressed to remember the routine practice or treatment policy of 1995 and to describe in coherent terms how it differed from that which was followed in 1985 or 2005. In many cases their grasp of the most basic elements of medicine appears to have slipped with the years: this may be unsurprising but it can be humiliating and distressing.

Limitation

Adult patients of sound mind must issue their writs in respect of personal injuries within 3 years of learning who caused their damage (*Limitation Act 1980* section 11). They do not need to know that the injury was caused by negligence, but they may well be able to argue that only when they knew that their treatment was inadequate did they realise that their injury was not caused by their disease process. The court has a discretion to extend time indefinitely when the interests of justice demand it (*Limitation Act 1980* section 13).

The difficulty for the paediatrician is that time does not run at all against the child under 18, or a patient under a disability. Thus, the survivor of a neonatal disaster has an unfettered right to issue a writ at any time prior to his 21st birthday. If at the age of 18 the young person does not know who or what has caused the damage, time will not start to run until he does. If he never becomes capable

of managing his own affairs his 3 years does not start to run until his death. Since individuals with cerebral palsy currently enjoy a life expectancy which sometimes differs only marginally from the national average, hospitals need to keep neonatal records for a very long time. They are advised to keep all records until the child is aged 26 but records of catastrophic cases should be kept for 80 years. This creates storage problems in the present twilight years of paper records. Whenever the trial takes place, the court will judge the case on the available evidence. When a child acquired cerebral palsy because 68 minutes had elapsed between the delivery of twins, it seemed that this was in part attributable to a difficulty in finding the registrar where obstetric services were split between two sites. No satisfactory explanation could be provided 17 years after the event. The court rejected the defendant's argument that the judge should be less willing to draw an adverse inference against the defendant whom delay had deprived of a proper opportunity to rebut the claim (*Bull & Wakeham v Exeter Health Authority* 1993).

Criminal cases

The doctor enjoys no privileged position under the criminal law of the land and allegations of homicide will be judged by the same rules as apply to the rest of society.

Murder

Murder consists of unlawfully killing a person with the intention of killing or causing grievous bodily harm. It can only be committed by a positive act, unlike manslaughter, which can be committed by omitting to act where there is a duty to do so. There is scope for argument about whether certain events are omissions or positive acts: switching off a ventilator is a positive act whereas ceasing to ventilate may be an omission, depending on the circumstances.

Manslaughter

Medical manslaughter is committed when a doctor causes the death of a patient as a result of an act or omission which amounts to gross negligence. Whether negligence is gross or not is a question of fact for the jury, but the prosecution must first demonstrate a breach of duty as judged by the *Bolam* test. The doctor who causes the death of a patient in the course of bona fide treatment without deliberately killing the child will not be guilty of any crime if she is acting in accordance with a respectable school of thought.

Where a neonatologist is called and finds a baby weighing 400 g, her first duty is to assess the baby. If she decides not to attempt resuscitation, or to abandon it if the baby does not respond, she cannot be guilty of a crime if a respectable school of thought would have taken the same view, because she will not be guilty of an act of negligence. The case will be judged in all the circumstances, so that a consultant at a major teaching hospital would not be able to rely solely on the fact that a reasonable paediatrician in a peripheral unit with poor facilities would have decided the case was hopeless. However, the burden will remain on the prosecution throughout to prove, so that the jury is sure, that no respectable neonatologist would have failed to resuscitate that child in those circumstances and that the failure to resuscitate did hasten death. Furthermore the negligent failure must be gross, so that the jury is sure that the action merits a criminal sanction.

Child protection law

Neonatologists need to be aware of the law in this area, particularly with respect to babies under their care whose parents have previous children in care for neglect or who are substance-abusing. All those involved in the care of children in hospital must have undergone level III child protection training.

Introduction

This chapter focuses on how our understanding of certain neonatal disorders has emerged and describes the research that underpinned it. Most advances are not the result of serendipitous discovery but are due instead to the gradual accumulation of research-based knowledge over an extended timeframe. Along the way, landmark publications appear and are highlighted in this chapter, but they need to be reviewed in the context of their building blocks.

Emerging care of the premature infant

The importance of feeding and warmth to the survival of premature infants had been known for centuries but it was not until the second half of the 19th century that serious efforts were made to improve their outcome. Two obstetricians, Stéphane Tarnier and Pierre Budin, led the way in Paris, France, at the Maternité and the Hôpital de la Charité.

Tarnier introduced hygienic measures at the Maternité which substantially reduced mortality from puerperal sepsis. He developed a closed incubator, and introduced gavage feeding in 1884. His pupil, Pierre Budin, had remarkably prescient ideas that were to occupy the minds of paediatricians into the 20th century. He developed what was probably the first follow-up clinic for infants and wrote about the outcome for premature babies in his treatise, *The Nursling*, which was originally published in 1900 and included information on breastfeeding and mother–infant bonding, hygiene, hypothermia and cyanotic episodes (Budin 1907).

Feeding the premature infant

The compromised ability of the feeble newborn to feed adequately, together with sepsis, were important causes of mortality before the 20th century. Methods of feeding premature babies included the trickling of milk into the infant's mouth directly from the mother's breast or from a wet nurse, and the use of spoons, small cups, drop-pers and quills.

Otto Heubner (1843–1926) is best known for the name of the branch of the anterior cerebral artery. An internal physician by training, he was subsequently appointed as Professor of Paediatrics in Berlin, Germany. His research with Max Rubner using indirect calorimetry to determine the caloric needs of infants promoted feeding according to requirements rather than empirical observations (Rubner and Heubner 1898, 1899; cited by Weaver 2009). The chemical composition of milk and its calorific value were known by the close of the 19th century and many felt that 100–150 cal/kg/day were optimal for growth, largely based on Rubner and Heubner's observations.

Although formula feeds based on evaporated cow's milk and approximating in composition to human milk were used by the second quarter of the 20th century, it was still widely considered that human milk was superior for premature infants. When Gordon and McNamara (1941) highlighted caloric loss in the stools resulting from the premature infant's difficulty in absorbing fat, their observations led to the increasing use of half-skimmed cow's milk preparations. In order to meet caloric needs the protein content had to be increased and the formulas also had a higher electrolyte and mineral content than human milk. Gordon et al. (1947) and later others showed that babies fed a half-skimmed milk formula gained weight more rapidly than those fed breast milk. The relatively high protein intakes were associated with raised blood urea levels (Omans et al. 1961).

However, there remained a concern that premature infants exclusively fed on expressed breast milk did not grow as well as those who received formula feeds. In a randomised trial Davies (1977) observed that babies of 28–32 weeks' gestation fed on expressed breast milk had significantly slower rates of head and linear growth in the first month of life compared with formula-fed infants.

In a review of nutritional studies Gordon and Levine (1944) commented that 'an optimum diet has been defined as one in which no change can promote greater health and well-being of the populace'. Therein lay an enigma that continues to challenge paediatric nutritional researchers. Is the aim to encourage growth in the early weeks that characterises normal fetal growth (Usher and McLean 1974); to satisfy some other concept of optimal postnatal weight gain; to permit accumulation of carbohydrate, fat and protein and minerals at a rate observed in the last trimester of pregnancy (Widdowson and Spray 1951); to influence later neurodevelopmental outcome in some way (Churchill 1963; Drillien 1964); or perhaps to minimise the risk of the infants developing adult disease such as hypertension, stroke and diabetes (Barker 1994)?

Early versus late feeding

By the late 1940s the practice of starting feeds at 24 hours or sooner ('early feeding') was causing concern because milk aspiration was considered to be a prominent cause of pneumonia and cyanotic episodes. Generalised oedema in the first week of life was also attributed to early feeding. In the USA and subsequently in the UK it became common practice to delay the first feed. For example, Gaisford and Schofield (1950) studied 231 premature babies in

whom the time of the first feed was determined by the baby's vigour. The average age when babies in different birthweight categories were offered their first feed ranged from 48 to 73 hours, but in many the delay was more than 100 hours. The authors concluded that a period of starvation was safe. Similarly, Crosse et al. (1954) described that feeding began on the third day in infants who weighed 3–4 lb (1.4–1.8 kg), and on the fourth day for those under 3 lb (1.4 kg).

During the 1960s evidence accumulated suggesting that early starvation might be causally related to cerebral palsy in premature infants (Churchill 1963; Drillien 1964). There was also growing experimental evidence in animals of the harmful effects of early malnutrition (McCance and Widdowson 1962).

In what proved to be a landmark publication, Smallpiece and Davies (1964) observed that infants who weighed 1000–2000 g could safely be fed within 2 hours of birth on undiluted breast milk at 60 ml/kg/day, increasing daily to 160 ml/kg/day. They suffered less symptomatic hypoglycaemia and their bilirubin levels were lower than those of infants who were fed later. Similar beneficial effects of early feeding were subsequently reported by others but it was several years before the practice became widely adopted. An excellent historical review of changing attitudes to the first feed and the underlying scientific concepts was written by Davies (1978).

Thermoregulation and the premature infant

The vulnerability of newborn infants exposed to a cold environment has been known from ancient times. Methods used to keep small and feeble babies warm included fireside heat, hot-water bottles, animal skins and plant leaves. Probably the first device which can be considered to be an incubator was a warming tub – a double-walled metal tub with the space between the walls filled with warm water. This was developed in 1835 and used at the Foundling Hospital in St Petersburg. The subsequent history of the development of incubators was addressed by Cone (1985).

The emergence of public viewing of babies nursed in incubators at various fairs and exhibitions in Europe and the USA from around 1896 until 1940 was addressed by Silverman (1979) in a captivating account. The incubator exhibitions did at least raise the profile of small babies and provide access to warmth and nutrition and for some it was their only hope of survival. Arguably it also stimulated an interest in the science of thermoregulation in infants.

Thermoregulation

From the early 1900s animal physiologists had studied birds and mammals, establishing that there was a critical environmental temperature below which heat production was necessary to maintain a normal body temperature and above which stability of temperature was dependent on physical factors such as changes in insulation and body posture (Scholander et al. 1950). The critical temperature varied between species and habitat. Given what was known about the lability of body temperature in small infants, and that heat loss occurred by evaporation, conduction, radiation and convection, a key question was how babies might protect themselves when exposed to a cool environment.

In 1943 Day and associates published their results of a detailed study of premature infants aged 4–53 days, in which heat production (oxygen consumption) and different forms of heat loss were measured in relation to environmental temperature. They observed that in cool air vasoconstriction was active but total heat loss per

unit area of skin was greater than that of adults. Although infants increased their heat production in cool air, 'the sustained muscular movement necessary to raise heat production is more difficult for these feeble subjects than for adults' (Day et al. 1943).

More than a decade later Silverman et al. (1958) in a randomised controlled trial observed that prematurely born infants nursed in incubators maintained at a temperature of 31.7°C during the first 5 days of life had a better survival rate than those nursed at 28.9°C (84% versus 68%). The beneficial effect was observed in all birth-weight categories.

Brück (1961) showed that infants from birth, including those of low birthweight, had a very well-developed thermoregulatory control system. They could adjust their peripheral blood flow and sweat secretion and the temperature threshold at which these controls were activated was related to body size. The increased heat production when infants were exposed to a cool environment was the result of non-shivering thermogenesis rather than shivering.

The metabolic response to a cool environment

Smith (1962) suggested that brown fat might be a source of heat production in the cold-adapted rat as oxygen consumption of the tissue was high. A major advance was a study by Dawkins and Hull (1964); these authors observed that exposure to cold was associated with a rise in temperature of brown adipose tissue. Hydrolysis of the fat was associated with a marked rise in plasma glycerol levels and a smaller increase in plasma free fatty acids, suggesting that most of the liberated free fatty acids was metabolised within the brown adipose tissue.

Silverman et al. (1964) observed that when babies were exposed to a cool environment the nape of the neck was warmer than other sites. The distribution of brown adipose tissue in the human infant at necropsy was studied by Aherne and Hull (1966), who showed that it was relatively depleted in infants who had died following a history of hypothermia or cold injury.

It is perhaps intuitive that the metabolic response of newborn babies to a cool environment might be influenced by their state of oxygenation. Cross et al. (1958) reported that oxygen consumption (metabolic rate) in premature and term babies decreased when they were exposed to 15% oxygen. They speculated that, although this might be a defence mechanism against hypoxia, it might also impair thermoregulation and that a low body temperature in the newborn might be symptomatic of hypoxia. Hill (1959) shed light on this issue in laboratory animals when she observed that it was only in a cool environment, when the metabolic rate had already increased to maintain body temperature, that induced hypoxia caused a fall in oxygen consumption and a fall in rectal temperature. In a neutral thermal environment induced hypoxia had no effect on oxygen consumption.

The neutral thermal environment for newborn babies

Additional clinical studies of thermoregulation in newborn babies emerged and closely reflected observation in animals. This culminated in defining the thermal environment for newborn babies that made minimal demands on the infant's energy reserves with core body temperature being regulated by changes in skin blood flow, posture and sweating (Hey and Katz 1970). The concept of thermal neutrality was later reviewed further by Hey (1975).

Respiratory distress syndrome

In 1903 Hochheim, reporting on a necropsy study in newborn infants, drew attention to infants whose alveolar ducts and alveoli were coated with a layer of eosinophilic material originally described as myelin. The next half-century saw intense research and debate about the origin and significance of this material, which was subsequently referred to as hyaline (from the Greek for glass). The suggested causes of the hyaline membranes included aspiration of amniotic fluid or vernix caseosa, infection, congenital or developmental anomaly, intrauterine hypoxia, oxygen poisoning, injury and necrosis of bronchiolar epithelium. The various aetiological theories put forward were based almost entirely on histochemical analysis of lung tissue with little in the way of clinicopathological correlation. Distressed breathing in premature infants was recognised but it was generally attributed to 'congenital atelectasis' or 'asphyxia'.

By the 1950s the association of hyaline membranes at necropsy with prematurity and respiratory distress was confirmed and the terms 'hyaline membrane disease' and 'idiopathic respiratory distress syndrome' became increasingly used. Gitlin and Craig (1956) concluded that the membranes were composed of fibrin formed in situ as a result of exudation of fibrinogen from pulmonary capillaries. The radiological features of the disorder were described and the reticular-granular pattern on chest X-ray was distinguished from the coarse opacities associated with amniotic fluid aspiration and pneumonia (Donald and Steiner 1953).

Pulmonary mechanics and surfactant

In 1929 von Neergaard compared the pressure-volume curves of air-filled porcine lungs with curves produced after filling the lungs with isotonic gum solution which had the potential to abolish surface tension forces at the air-tissue interface. Based on these experiments he suggested that surface tension forces were more important than elasticity in lung recoil, and that surface forces might interfere with lung expansion. The importance of this was not appreciated at a time when there was still growing preoccupation with the significance of hyaline membranes.

Gruenwald (1947) suggested that an unusually high surface tension might be responsible for the uneven pattern of expansion observed in the lungs of premature infants and for resistance to lung inflation. During the 1950s the relationship between the pressure-volume characteristics of lung and surface tension force became clarified. Pattle (1955), studying nerve gases at the Ministry of Defence at Porton Down, UK, observed that foam found in the trachea of rabbits with induced acute lung oedema had an altogether peculiar property in that it was unaffected by silicone anti-foams. He concluded that the stability of the foam was due to an insoluble surface layer on the foam bubbles which originated from the original lining of the air spaces.

At the same time researchers from the Department of Physiology at the Harvard School of Public Health were studying pulmonary mechanics and the implication of surface tension forces at the air-liquid interface. Radford (1954) calculated the internal surface area of the lungs from their pressure-volume characteristics assuming that surface tension was constant and equal to that of plasma. His calculation of the surface area was much lower than data derived from morphological examination. This anomaly held a clue to the surface-active property of the lung lining.

Clements (1957) studied surface films prepared from rat, cat and dog lungs using a modified Wilhelmy balance, which compresses and expands the surface film while measuring surface tension. He

showed that surface tension fell to a minimum as the surface area of the film was compressed, but, more importantly, only a 10% expansion from the compressed state restored the surface tension to its maximum value – the surface film was showing hysteresis. In the absence of the specialised surface film, which Clements referred to as pulmonary surfactant, the high surface tension would resist lung expansion, cause small air spaces at high pressure to empty into larger air spaces and promote uneven expansion and atelectasis.

The association of surfactant deficiency with hyaline membrane disease was established by [Avery and Mead \(1959\)](#), who measured the surface tension of lung extracts of infants using a Wilhelmy balance. The extracts from infants who weighed more than 1200 g and who had died from causes other than hyaline membrane disease achieved much lower surface tensions than lung extracts from infants who had died from hyaline membrane disease and from smaller babies.

Thus, more than half a century after Hochheim's original description of hyaline membranes, the underlying physicochemical abnormalities of the lungs were discovered. [Gandy et al. \(1970\)](#) revisited the histopathological changes in the lung in hyaline membrane disease and measured surface tension in lung extracts. They observed that the presence or absence of osmiophilic granules, which represent stored surfactant within type 2 pneumocytes, did indeed reflect surface tension measurements.

Antepartum glucocorticoids for the prevention of respiratory distress syndrome

[Liggins et al. \(1967\)](#), while studying the influence of the fetal endocrine system in promoting parturition in ewes, observed that ablation of the fetal pituitary or hypothalamus led to prolongation of gestation. Stimulation of the fetal adrenals by corticotrophin or infusion of cortisol led to premature parturition ([Liggins, 1968, 1969](#)). A striking feature was that lambs born at 117–123 days' gestation following dexamethasone infusion showed partial expansion of their lungs, a feature which is not normally apparent at this gestation and which is dependent on adequate surfactant activity. Liggins suggested that the dexamethasone-treated fetuses may have had accelerated surfactant production.

[DeLemos et al. \(1970\)](#) extended these observations in a novel way. They infused cortisol into one of twin fetal lambs and observed that the lungs of treated lambs were more mature than their untreated twins in terms of pressure–volume curves and surface tension measurements of lung extracts. Similar evidence for hormonal control of fetal lung development has been shown in the rabbit ([Chiswick et al. 1973](#)).

Supporting evidence for the hormonal control of pulmonary surfactant development in human fetuses was provided in an autopsy study by [Naeye et al. \(1971\)](#). They observed that infants who had died with hyaline membrane disease had lighter adrenal glands than those dying from other causes and infection arising before birth was correlated with the absence of hyaline membrane disease. Anencephalic infants with no adrenal fetal cortical zone had a reduced mass of osmiophilic granules in their type 2 pneumocytes compared with non-anencephalic infants.

The first controlled trial of antepartum glucocorticoid treatment for the prevention of respiratory distress syndrome (RDS) commenced in December 1969 and enrolled 282 mothers admitted in preterm labour or in whom delivery was planned before 37 weeks ([Liggins and Howie 1972](#)). RDS was seen significantly less in infants of mothers treated with betamethasone but this was confined to infants under 32 weeks' gestation whose mothers had been treated

for at least 24 hours before delivery. Neonatal mortality was significantly reduced, and there were no deaths with hyaline membrane disease or intraventricular haemorrhage among infants of mothers who had received betamethasone longer than 24 hours before delivery.

This important trial was the forerunner of many others which shed light on whether there was a true gestational age cut-off point below which antenatal glucocorticoids were ineffective, whether repeated doses of glucocorticoids were beneficial, and whether there were maternal contraindications to their use.

Treatment of respiratory distress syndrome

Before the discovery of surfactant deficiency as the underlying cause of RDS, treatment was largely supportive and relied on oxygen, intravenous fluids and the maintenance of acid–base balance. The use of supplemental oxygen suffered a setback with its restrictive use because of fears about retrolental fibroplasia. This was associated at the time with a rise in mortality from RDS ([Avery and Oppenheimer 1960](#)).

Mechanical ventilation

The experimental use of positive-pressure mechanical ventilation for newborn infants with hyaline membrane disease was reported by [Donald and Lord \(1953\)](#). During the 1960s, with further experience limited to a few specialist neonatal units, the practical problems became apparent, especially the challenge of prolonged mechanical ventilation including endotracheal tube instability and problems maintaining nutrition. Intuitively it was felt that the treatment carried huge risks and that it was a last resort for infants dying with hyaline membrane disease. The third child of President John F Kennedy died of RDS, having been delivered at 34 weeks weighing 2.11 kg in August 1963. His obituary in the *New York Times* stated that all that could be done was to 'monitor the infant's blood chemistry and to try to keep it near normal'. The following year, [Delivoria-Papadopoulos and Swyer \(1964\)](#) described their experience of mechanical ventilation of severely acidaemic and apnoeic infants with 'terminal' hyaline membrane disease and concluded that the best hope of success with this treatment was its application in the preterminal rather than the terminal state.

The growth of neonatal intensive care units and the development of regional referral centres in the UK during the 1970s led to an increasing experience of mechanical ventilation in infants with RDS. A major concern was the occurrence of pneumothoraces and bronchopulmonary dysplasia, which [Northway et al. \(1967\)](#) had originally described. For staff on the emerging intensive care units assisted ventilation was a steep learning curve because ventilators had hitherto been machines used by anaesthetists – not paediatricians. An important advance, certainly in the UK, were publications by [Reynolds \(1971\)](#) and [Herman and Reynolds \(1973\)](#) describing the effect of alterations of ventilator settings on pulmonary gas exchange in hyaline membrane disease and the use of strategies that might minimise high inspired concentrations of oxygen and high peak inspiratory pressures.

[Gregory et al. \(1971\)](#) reported the successful use of continuous positive airway pressure (CPAP) in spontaneously breathing infants with RDS. Different methods of applying CPAP emerged but the influence on clinical practice was that it drew attention to the benefits of respiratory support of some kind before the infant had reached a terminal state of respiratory failure.

During the subsequent decades advances occurred at a rapid pace. Non-invasive continuous blood gas monitoring facilitated the earlier detection of deteriorating infants. Interest grew in different

ventilator strategies aimed at reducing the risk of barotrauma. Sedative drugs and muscle relaxants were increasingly used. However, the major advance – the one that really improved survival rates in RDS – was surfactant replacement therapy.

Surfactant replacement therapy

Based on their notion that pulmonary ischaemia was very important in the pathogenesis of RDS, [Chu et al. \(1967\)](#) conducted a detailed cardiorespiratory function study of infants with the disease. Intravenous acetylcholine was associated with an increase in effective pulmonary flow and appeared to have other beneficial functional effects. Administration of dipalmitoyl lecithin by aerosol was followed by an increase in lung compliance but this occurred even in infants who subsequently died and there was no apparent clinical benefit.

The effect of natural surfactant derived from rabbit and bovine lung was tested on premature animals during the 1970s with encouraging results. [Fujiwara et al. \(1980\)](#) treated 10 premature infants with severe hyaline membrane disease by intratracheal administration of an artificial surfactant modified from bovine lung tissue. Oxygenation improved and it was possible to reduce the ventilator settings. Eight infants survived.

During the 1980s synthetic and bovine or porcine-derived surfactants were used in many randomised controlled trials and treatment reduced mortality and pulmonary air leaks. Further trials have compared different types of surfactant, examined more critically the role of multiple versus single dosage and shown that prophylactic treatment soon after delivery is more beneficial than rescue treatment. [Halliday \(2008\)](#) has provided an excellent review of the development of surfactant replacement therapy.

Intraventricular haemorrhage

During the early part of the 20th century it became clear that intraventricular haemorrhage (IVH) was seen more commonly in premature infants. [Browne \(1922\)](#) drew attention to the association of IVH and premature birth 'even when the delivery had been easy and natural' and he attributed this to 'the great delicacy of the vessels in the premature fetus'. The early debate about the cause of IVH essentially focused on the anatomical origin of the bleeding. It was thought that the source of the bleeding was engorged veins of the choroid plexus or from the subependymal region with leakage into the ventricular cavity. Attention was focused on engorgement of the terminal vein which drains the subependymal region.

The pathological anatomy was advanced by the study of [Hambleton and Wigglesworth \(1976\)](#), who used a dye injection and stereomicroscopic method to examine the brains of babies who had died within 10 days of birth. Among premature infants with subependymal haemorrhage or IVH they were unable to confirm rupture of the terminal vein or germinal layer infarction. They observed a rich capillary network within the germinal layer which was supplied by Heubner's artery, a branch of the anterior cerebral artery. Injection of the carotid artery caused prominent leaks within the germinal layer capillary bed. The authors speculated that the capillaries might rupture by a rise in arterial pressure in conditions of hypercapnia or hypoxia.

Enlarging on this, [Wigglesworth and Pape \(1978\)](#) suggested an integrated model which might explain both haemorrhagic and ischaemic lesions in the preterm brain. The model took into account the state of development of the cerebral vessels and the effects thereon of increased or decreased perfusion pressure in precipitating haemorrhagic and ischaemic lesions.

As the use of mechanical ventilation for babies with RDS was evolving, death from IVH appeared to be an important limiting factor. A major advance was the ability to diagnose IVH in life by computed tomographic brain scanning ([Papile et al. 1978](#)) and ultrasound imaging ([Pape et al. 1979](#)). The importance of the paper by [Papile and her collaborators \(1978\)](#) was their grading of the extent of the IVH (grades I–IV).

Ultrasound imaging proved to be more convenient as a cot-side investigation and it became established as an important research tool. Many studies were published seeking to relate obstetric and neonatal factors with IVH. A plethora of 'risk factors' emerged which were difficult to interpret because of confounding variables but they appeared to have had their basis in altered regulation of cerebral blood flow, sudden changes in blood volume and coagulation abnormalities.

Ultrasound imaging made it possible to assess the effects of various agents for reducing the risk of IVH such as phenobarbital ([Donn et al. 1981](#)), vitamin E ([Chiswick et al. 1983](#)), etamsylate ([Cooke and Morgan 1984](#)) and indometacin ([Ment et al. 1985](#)). None of those agents became firmly established or stood the test of time, although indometacin has enjoyed a recent revival. This was possibly because the background incidence of IVH fell as a result of improvements in obstetric and neonatal care such as the use of antenatal corticosteroids, surfactant replacement and efforts to promote circulatory stability. Long-term outcome studies from the various prophylaxis regimens were few.

Periventricular leukomalacia

The pattern of pathology that we now term 'periventricular leukomalacia' (PVL) was described in the 19th century under a different name ([Virchow 1867](#)). The first comprehensive description of PVL was by [Banker and Larroche \(1962\)](#) and was based on postmortem examinations of infants set against a review of neuropathological observations that had been made in the 19th century. They used the term 'periventricular leukomalacia' to reflect their observation of bilateral 'necrosis of the white matter dorsal and lateral to the external angles of the lateral ventricles' and suggested a relationship with a compromised arterial supply.

The vascular anatomy and its relationship to PVL were clarified by [De Reuck et al. \(1972\)](#), who showed that the lesions were located in the periventricular arterial border zones between the ventriculopetal and ventriculofugal branches of the deep penetrating arteries and suggested that impaired perfusion was an aetiological factor. In a postmortem study of infants with PVL, [Armstrong and Norman \(1974\)](#) observed that most had suffered perinatal complications or had been born prematurely. They noted that haemorrhage occurred within infarcts in some infants and differentiated this from subependymal-related haemorrhage. They observed that cavity formation in the infarcted areas was associated with degeneration of the corticospinal tracts and speculated that this may form an anatomical basis for spastic hemiplegia or quadriplegia.

During the 1980s descriptions of the cerebral ultrasound appearance of PVL appeared. The ultrasound characteristics of haemorrhagic periventricular leukomalacia and their correlation with autopsy findings were described by [Hill et al. \(1982\)](#). The reported incidence of PVL ranged from less than 5% ([Calvert et al. 1986](#)) to 18% ([Sinha et al. 1985](#)). As with IVH, these studies allowed associated clinical factors to be explored. Subsequent reports suggested that neonatal cranial ultrasound expressions of white-matter damage were reasonably good predictors of neurodevelopmental outcomes ([Fawer et al. 1987](#)).

Meanwhile both experimental and clinical evidence accumulated to suggest an association between a maternal or fetal inflammatory response and white-matter injury. Gilles *et al.* (1976) had shown that intraperitoneal injection of lipopolysaccharides into kittens caused white-matter changes not dissimilar to that seen in humans. Elevated levels of proinflammatory cytokines in umbilical cord plasma and amniotic fluid (Yoon *et al.* 1996, 1997) were reported to be associated with PVL, and other studies showed that clinical markers of intra-amniotic infection preceding premature birth are linked to white-matter damage.

Necrotising enterocolitis

During the 19th century and first half of the 20th century there were many published reports of newborn infants with intestinal perforation. Most of these cases were likely to be perforations secondary to intestinal obstruction and caused by congenital bowel malformations or meconium plugs, but in others there was no evidence of obstruction.

Thelander (1939) summarised the published cases of bowel perforations that were unassociated with obstruction and considered that infection might have played a role. In 1944 Willi observed ulceration or perforation of the terminal ileum or large bowel at postmortem in infants under 3 months who had died with symptoms of severe enteritis. He called this condition 'malignant enteritis' but was unable to isolate any causative organism. Similar cases with ulcerated lesions of the gut were reported as 'enterocolitis ulcerosa necroticans'. Although the vulnerability of the preterm infant to this disorder became apparent there was continuing uncertainty about the aetiology.

Corday *et al.* (1962) drew attention to a syndrome in adult patients characterised by unexplained haemorrhagic and necrotic lesions of the gastrointestinal tract associated with a range of remote systemic disturbances such as myocardial infarction, shock states and severe burns. In a series of experiments, cardiac arrhythmias and haemorrhagic shock were induced in mongrel dogs and resulted in increased vascular resistance of the arteriolar bed supplying the bowel wall due to angiospasm.

Lloyd (1969) observed that 80% of the infants who suffered gastrointestinal perforations experienced a significant episode of asphyxia or shock during the perinatal period. Drawing on the research observations of physiologists who had studied the mechanisms that allow diving mammals to operate successfully in deep water and on Corday's observations in adult patients, Lloyd postulated that perforations of the gastrointestinal tract were the result of ischaemic necrosis related to an asphyxial defence mechanism characterised by selective circulatory ischaemia.

Outbreaks of necrotising enterocolitis were widely reported in the 1970s but no single organism has been consistently associated with the disease. As the decade progressed it became clear that enteral feeding including the rapid advancement of feeds was a provoking factor especially in preterm infants and the condition was seen less frequently in infants who were solely fed on human milk. More recently, attention has focused on the aetiological role of immunological defence mechanisms of the gut, especially in preterm infants.

Retinopathy of prematurity

The authoritative account of the discovery of retinopathy of prematurity (ROP) (Silverman 1980) described how Stewart Clifford, a Boston paediatrician, observed nystagmus and opacities in the eyes of a 3-month-old premature girl in 1941. Subsequent examination under anaesthesia revealed a grey membrane covered with blood

vessels which appeared to be behind the lens and both eyes were affected.

Terry (1942) described five premature infants with 'fibroblastic overgrowth of a persistent vascular sheath behind each crystalline lens'. The term 'retrolental fibroplasia' (RLF) was coined shortly after. By 1946 he had seen more than 100 cases, with 75% occurring in babies who weighed 3½ lb (1.6 kg) or less. He was aware of apparent variations in the frequency of RLF in different medical centres and suggested that individual differences in technique of premature infant care in these centres may act as an aetiological factor (Terry 1946). Sadly he would never know the fruits of his observations as he died of a heart attack in the same year.

Based on serial ophthalmoscopic examinations of premature infants from birth, Owens and Owens (1948) described the progressive vascular changes in the retina that preceded the fibrotic changes behind the lens. Numerous causes were suspected not directly related to the role of oxygen, including precocious exposure to light, vitamin E deficiency, supplemental iron and water-soluble vitamins, and blood transfusions. Reports of RLF soon appeared from England and other countries.

Role of oxygen

Kinsey and Zacharias (1949) first mooted that oxygen therapy might be related to RLF on the basis that infants who developed the disorder tended to come from nurseries where oxygen was more likely to be administered. Campbell (1951) reported her experiences of RLF in Melbourne, Australia, where the first cases appeared in 1948 and coincided with the introduction of the 'oxygen cot' which supplied oxygen in concentrations of 40–60%. The incidence of RLF in premature babies was 18.7% whereas the incidence in other premature babies who had apparently received oxygen in a more restricted way was 6.9%.

Similarly, Crosse and Evans (1952) reported from Birmingham, UK, that during 1931–1947 there had been no recorded cases of RLF, whereas a policy of liberal oxygen administration from January 1949 to June 1950 was associated with an incidence of severe RLF of 10.2%.

In the same year Jefferson (1952) reported her follow-up examination of more than 600 infants nursed at two premature baby units in Manchester, UK, from 1947 to 1951. The incidence of RLF ranged from 3% in those more than 4 lb (1.8 kg) at birth, to 41% in those less than 3 lb (1.4 kg). She observed that cases began to appear when oxygen tents were introduced and it was later confirmed that the concentration of oxygen in the tents could reach 60% even at the lowest flow rate of 0.5 l/min.

However, the debate about oxygen as a cause continued, with some arguing that it was sudden removal from an oxygen-rich environment that was causal and that relative hypoxia might have a role (Szewczyk 1952). Ashton *et al.* (1953) observed obliteration of the retinal vessels when young kittens were exposed to 60–80% oxygen for several days. Transfer of the animals to air led to a reopening of some vessels but many were permanently obstructed and the reformed network was grossly abnormal with revascularisation extending into the vitreous, haemorrhages and retinal detachment.

The National Cooperative Study

A multicentre study was started in the USA in 1953 to determine whether oxygen administration was implicated in RLF. The cooperative study enrolled infants who weighed 1500 g or less and had survived 48 hours (Kinsey and Hemphill 1955). Among singletons who received more than 50% oxygen for 28 days the incidence of

vascular changes of RLF (70%) and of scarring RLF (17%) was significantly higher than in those whose oxygen concentration was limited to less than 50% and based on clinical needs (RLF 31%, scarring RLF 5%). Very soon after these results were published it became routine practice to limit oxygen supplementation to no more than 40–50% and as a result few cases of RLF subsequently occurred.

The curtailed use of oxygen at a time when arterial oxygen levels were not measured was associated with increased mortality from hyaline membrane disease (Avery and Oppenheimer 1960). Similarly, the restricted use of oxygen in the UK was associated with increased mortality in the first 24 hours after birth (Cross 1973) and led the author to plead for the wider use of arterial oxygen monitoring in special care baby units.

The 'new' retinopathy of prematurity

There appeared to have been a resurgence of ROP from the late 1970s affecting very premature infants and progressing to cicatricial disease and not wholly explicable by excess use of supplemental oxygen. A major landmark was the publication of the Committee for the Classification of Retinopathy of Prematurity (1984) as this facilitated research including therapeutic trials of cryotherapy and subsequently laser photocoagulation based on proper evaluation of the stage and distribution of the disease. Although our knowledge of the causes of ROP in very premature babies is still incomplete, a major step forward was our understanding of the role of vascular endothelial growth factor and insulin-like growth factor 1 in its pathogenesis.

Birth asphyxia

Animals respond to an asphyxial insult by apnoea followed by gasping, which becomes weaker and ceases in the absence of resuscitation. The time interval between the onset of the asphyxial insult and the last gasp has been used as a proxy for an animal's relative tolerance to asphyxia and it became a helpful tool in studying the physiological changes that occur in asphyxia.

Greater tolerance of the young to asphyxia

Le Gallois (1812), cited by Dawes (1968, p. 143), observed that following an asphyxial insult in animals the time to the last gasp was longer with decreasing age after birth. The greater tolerance of the newborn animal to asphyxia was subsequently confirmed by many other researchers and seemed counterintuitive to the idea that the young are less resilient.

Effect of environmental temperature

It had been known since the 19th century that a low environmental temperature prolonged the time to the last gasp in asphyxiated animals. Speculation about the mechanism of prolonged gasping in a cold environment centred on reduced metabolic demand of the brain and heart.

Westin et al. (1962) described 10 severely asphyxiated term infants who had not responded to positive-pressure ventilation. They were immersed supine in a bath of running cold water at 4.5–14°C from 4 to 39 minutes as determined by the onset of regular breathing, although all infants apparently responded promptly with an improvement in heart rate, colour and muscle tone. The lowest rectal temperatures ranged from 23 to 32°C. All but one infant survived, apparently without neurodevelopmental impairment.

Subsequent research showed that rapid cooling of asphyxiated fetal monkeys during secondary apnoea did not hasten recovery (Daniel et al. 1966) and interest waned with a better understanding of the pathophysiological sequence of events following asphyxia in newborn babies, and the crucial role of positive-pressure ventilation, and maintenance of the circulation in a thermoneutral environment.

Circulation and cardiac glycogen

Le Gallois (1812) attached importance to the maintenance of the circulation during asphyxia in newborn animals and observed that in rabbits the time to the last gasp was reduced when the circulation was interrupted by removal of the heart. Similar observations were made more than a century later across a range of newborn species.

The importance of carbohydrate as an energy source in asphyxiated young animals was shown by Himwich et al. (1941) in experiments on newborn rats asphyxiated in 100% nitrogen. Prior injection of inhibitors of anaerobic glycolysis (sodium iodoacetate or sodium fluoride) led to a reduction in gasping time. Dawes et al. (1959) showed that, following umbilical cord ligation in immature lambs, the time to the last gasp was positively related to levels of cardiac glycogen at different gestational ages.

These observations were extended by Dawes et al. (1963), who observed in lambs that, if glycolysis was maintained during asphyxia by administration of glucose and base sufficient to reduce the fall in arterial pH, the circulation was maintained longer than in untreated lambs.

Sequence of circulatory and respiratory changes following asphyxia

Dawes et al. (1960) described the sequence of events that occur when near-term fetal monkeys were asphyxiated at delivery by ligation of the cord with the head covered in a bag of saline. A brief period of respiratory activity was followed by apnoea (subsequently referred to as primary apnoea) which lasted up to 1 minute or so. Gasping then ensued and gradually became weaker, culminating in the last gasp and the onset of terminal apnoea. The average time to the last gasp was about 8 minutes, following which death ensued without resuscitation. Soon after the asphyxial insult the heart rate fell steeply and remained slow unless resuscitation occurred. Blood pressure rose transiently at first and then progressively fell. This sequence has been instrumental to our understanding of birth asphyxia and resuscitation in human babies.

Assessment of vital signs at birth and resuscitation

Virginia Apgar, commenting on resuscitation in the introduction to her landmark paper (Apgar 1953), wrote: 'Seldom have there been such imaginative ideas, such enthusiasms, and dislikes, and such unscientific observations and study about one clinical picture'. At that time there was no standardised way of describing the 'one clinical picture' she referred to – the state of the baby at birth.

The importance of her method of assessment was that it brought together in one score the circulatory, respiratory and neurological variables that were relevant to the evolving research into the pathophysiology of birth asphyxia. Her interest was driven by her wish to study the effects of caesarean section and maternal pain relief on the baby's condition at birth. The score was not used to determine when babies needed resuscitation but she subsequently

recommended that the assessment should be extended beyond 1 minute in those babies who required resuscitation.

Descriptions of resuscitation of newborn babies have their origins in ancient texts and it would serve little purpose to highlight those except to promote a sense of incredulity. In 1966 Cross published an informative account of resuscitation of the asphyxiated newborn drawing on the extensive scientific literature that had accumulated by that time.

Birth asphyxia and brain damage

In a controversial presentation to the Obstetric Society, London, UK, in 1861, Little proposed an association between difficult delivery, asphyxia, prematurity and congenital spastic paralysis (Little 1862). The term 'cerebral palsy' was coined later by William Osler. Little's theories were later challenged by Freud in a series of monographs culminating in his classic book on infantile cerebral palsy (Freud 1968). Freud agreed that some cases of cerebral palsy were associated with birth complications but argued that birth complications and cerebral palsy might be the result of the same earlier developmental abnormality of the brain.

Studies of asphyxia in newborn guinea pigs had shown histological changes in the central nervous system (Windle and Becker 1942). In newborn Rhesus monkeys acutely asphyxiated by detaching the placenta at hysterotomy while keeping the fetal membranes intact for 11–16 minutes before resuscitation, a common pattern of symmetrical damage to brainstem and basal ganglia nuclei was observed with the cerebral cortex less severely affected (Ranck and Windle 1959).

Myers et al. (1969) induced partial asphyxia in fetal monkeys by oxytocin-stimulated contractions and showed that many had evidence of brain swelling and neuronal damage. Subsequently, different approaches to inducing chronic partial asphyxia were used including maternal hypotension and partial placental ablation. In an extensive review, Myers (1972) drew attention to the importance of hypotension and severe metabolic acidaemia as a prelude to brain damage, and that damage followed 30 minutes to several hours of partial asphyxia. Brain swelling was often a feature associated with damage to the cerebral cortex with less involvement of the brainstem, basal ganglia and thalamus. This contrasted with the earlier studies of Ranck and Windle (1959) where the main damage was to brainstem nuclei rather than the cerebral cortex.

Birth asphyxia and neonatal encephalopathy

By the 1960s it had become clear that babies who had abnormal neurological signs as newborns were at an increased risk of neurodevelopmental abnormalities in later months and years and some of these babies had a history of fetal distress and depressed vital signs at birth.

The importance of neonatal encephalopathy as a risk factor for a poor outcome in babies with birth asphyxia was clarified by a survey of more than 54 000 pregnant women cared for in maternity hospitals in the USA between 1959 and 1966 (Nelson and Ellenberg 1981). Among surviving children with Apgar scores of 0–3 at 10–20 minutes, 82% escaped cerebral palsy but the children with cerebral palsy were characterised by the occurrence of seizures within 24 hours of birth.

Sarnat and Sarnat (1976) characterised the clinical features of the encephalopathy in newborn infants who had a prominent history of fetal distress or a low Apgar score at 1 or 5 minutes. They were able to define three stages based mainly, but not exclusively, on their level of arousal, presence of seizures and primitive reflexes. Subsequently many studies showed the importance of the severity of the

encephalopathy in determining neurodevelopmental outcome (Peliowski and Finer 1992).

Rhesus haemolytic disease

For centuries it had been observed that some babies were born severely oedematous and pale and died shortly after birth. In those who lived a little longer severe jaundice was a prominent feature. The terminology for what were thought to be separate conditions was 'universal oedema of the newborn', 'congenital anaemia of the newborn', and 'icterus gravis neonatorum'; if the liver and spleen were enlarged and there was erythroblastic activity in peripheral blood the term 'erythroblastosis fetalis' was used.

Diamond et al. (1932) concluded that universal oedema, familial icterus gravis neonatorum and anaemia of the newborn were closely related and were caused by the same underlying pathological process with haemolysis and erythroblastosis being common to all.

Darrow (1938), a pathologist who herself experienced a series of perinatal losses from erythroblastosis fetalis, suggested that the cause of the fetal haemolysis was the transplacental passage of fetal red blood cells to the mother, who produced antibodies which subsequently found their way into the fetal circulation. The discovery and naming of the Rh antigen are generally attributed to Landsteiner and Weiner (1940), who injected blood from rhesus monkeys into rabbits and guinea pigs. When the derived antisera were tested against human blood samples, 85% were Rh-positive.

Infants with erythroblastosis fetalis were often treated by simple blood transfusion. In 1943 Mollison reported that the survival time of rhesus-positive red blood cells in these babies was considerably shorter than that of transfused rhesus-negative red cells. The outcome of transfused babies remained poor until a convenient method of exchange transfusion was introduced by Diamond in 1946 which utilised catheterisation of the umbilical vein. He described his experience in an address to the American Academy of Pediatrics (Diamond 1948). The major contribution of exchange transfusion to the management of rhesus haemolytic disease was underlined by Mollison and Walker (1952), who showed that infants treated by exchange transfusion had an improved survival rate and a lower incidence of kernicterus.

The prediction of the severity of rhesus haemolytic disease before birth attracted attention because many infants were stillborn. The estimation of serum rhesus antibody titres in the mother were of limited benefit in safely timing preterm delivery. The management of affected pregnancies took a leap forwards following Liley's observations that amniotic fluid bilirubin levels measured by spectrophotometry, as described earlier by Bevis (1953), were good predictors of fetal risk (Liley 1961). The outcome for affected fetuses was improved still further by intrauterine transfusion (Liley 1963).

The successful prevention of rhesus haemolytic disease by immunisation of mothers followed a string of research findings including the introduction of the Kleihauer–Betke staining technique for the detection of fetal erythrocytes in maternal blood; the detection of fetal erythrocytes in the blood of Rh-negative mothers after delivery (Finn et al. 1961); observations that ABO incompatibility afforded protection against Rh sensitisation (Nevanlinna and Vainio 1956; Stern et al. 1956); and the finding that anti-Rh (anti-D) protected against sensitisation in Rh-negative volunteers injected with rhesus-positive blood (Finn et al. 1961). These research observations culminated in the first reports of the successful prevention of Rh immunisation in high-risk pregnant women by Clarke and Sheppard (1965) in Liverpool, UK, and Freda et al. (1965) in New York, USA.

The nature and structure of a gene

Genetics is traditionally defined as the science of biological variation, and has been a scientific discipline for over a century. Human genetics makes up a large part of the field of genetics, but the principal laws of genetics are universal and apply equally to all species, including humans. Mendel's studies in the 19th century were originally felt to have no relevance to humans, and it is only in retrospect that their importance can be seen. Many of the principles of genetics were discovered through the study of smaller organisms, such as bacteria, yeast and fruit flies. The basic genetic mechanisms of cell division, development and differentiation happen in the same way in widely divergent species. Therefore, it is impossible to look at human genetics in isolation and there are large amounts of information from lower species which have a bearing on human disorders. The study of the genetics of small organisms has had a

profound impact on our understanding of human development, and of how human diseases develop. It is likely that such basic science will continue to contribute significantly to the understanding of human genetic disease. In this chapter, I hope to outline the basic elements of genetics, and describe the types of genetic tests now available to help in neonatal diagnosis.

The basic unit of inheritance for any species is the gene. The original concept of a gene arose long before the relationship between genes and nucleic acids was ever understood. A gene was considered to be a stable heritable element which conferred a particular property or phenotype on an individual organism. This element was passed on to subsequent generations of a particular species, and the nature of the phenotype varied according to the nature of the gene. The concept of dominant and recessive traits, which will be discussed below, was derived from studies of inheritance patterns, long before the molecular basis of the gene was understood.

A gene can also be considered in another way, as a specific length of deoxyribonucleic acid (DNA) which encodes a particular function, in most cases the synthesis of a protein. This also is a stable heritable unit. Each cell in an organism, regardless of its function, has the entire set of genes for that particular organism, but only a proportion of those genes will be active. DNA is found in the nucleus of every cell of an organism, as a double helix (Fig. 8.1).

Each strand of the double helix has a backbone of alternating phosphate and deoxyribose sugar molecules, with the sugars attached to the 5' and 3' hydroxyl groups of the phosphate group. Attached to the sugar molecule, lying within the helix, is one of four nitrogen-containing nucleic acid bases. Two of these bases, adenine (A) and guanine (G), are purines, and two are the smaller pyrimidines cytosine (C) and thymine (T). The A and T bases pair together by hydrogen bonding, and the G and C bases similarly pair by hydrogen bonds (Fig. 8.2). The two strands of the double helix are held together by paired A–T or G–C bases of opposite strands of the double helix. The DNA strand can be read in only one direction, from 5' (left hand) to 3' (right hand). The two strands of DNA are complementary to each other, and the sequence of one strand can be predicted from its opposite. If one strand reads 5'-CAGCGTA-3', then the opposite strand must read 5'-TACGCTG-3'. The double-stranded sequence would then be written as below:

5'-CAGCGTA-3'
3'-GTCGCAT-5'

Fig. 8.1 Structure of a DNA chain. The deoxyribose and phosphate residues are linked to form the sugar-phosphate backbone.

The simplicity of the double-helix structure allows for several important functions for DNA.

First, huge amounts of information can be stored in the DNA strand. If a molecule of DNA is 1 million bases long, then there are $4^{1,000,000}$ possible sequences for that stretch of DNA. A genome is the complete DNA sequence of an organism. In humans, the estimated genome size is 3×10^9 basepairs (bp). The draft DNA sequence of the entire human genome has been completed, which is a major milestone in human scientific development. It is estimated that the genome has between 22 000 and 25 000 genes. However, despite the DNA sequence being available, the detailed function of many of these genes remains unknown. The next step after the sequencing of the human genome is the understanding of the complexities of all the human genes. The routine practical clinical application of the knowledge of the human genome is still some way off.

Second, the double helix provides a framework for DNA replication. One strand of DNA acts as a template for the synthesis of a new strand. The double helix unwinds, allowing DNA replication enzymes access to the template strand of DNA. The replication system builds a new strand of DNA based on the template. The new double helix formed as a result will contain one original strand and a newly synthesised complementary second strand. This is the basic mechanism of DNA replication in all species.

Third, the double helix provides a basis for repair of damaged DNA. A damaged base can be replaced, knowing its complementary base is present on the opposite strand. Damage to the

Fig. 8.2 Double-helix structure of DNA. The double helix of deoxyribose and phosphate molecules is held together by paired purine and pyrimidine bonds.

sugar-phosphate backbone can also be repaired using the opposite strand as a template.

Decoding the information in DNA

About 90% of the DNA in the human genome does not code for any specific property; only about 10% of the genome actually contains coding information in the form of a gene. In simple terms, the genetic code in DNA is transcribed into a molecule called messenger RNA (mRNA). The mRNA is then translated into a protein, which carries out the function encoded by the specific DNA.

A gene has several distinct elements (Fig. 8.3). The major part of the gene is divided into coding regions, called exons, and non-coding regions, called introns. Just before (5') the first exon, there is a promoter which indicates where transcription of a gene should start. There can be several promoters for one gene, and different promoters can be used according to the tissue in which the gene is being expressed; in other words, the promoter is tissue-specific. Further 5' of the promoter there can also be enhancers or suppressors, which can increase or decrease the level of transcription of the gene. Not all of the mRNA will code for protein, as some exons will code for mRNA that does not directly encode protein. These areas, known as untranslated regions, can be either at the start (5') or the end (3') of the mRNA.

To express the DNA code, mRNA is used. There are several different types of RNA, but mRNA is the most important in decoding DNA. There are three differences between RNA and DNA. First, the sugar backbone of RNA contains ribose rather than deoxyribose. Second, mRNA exists as a single strand, and remains more unstable.

Table 8.1 The genetic code

**Fig. 8.3** An idealised gene.

Third, in RNA, the base uracil (U) is used instead of thymine, whereas the other three nucleic acids remain the same.

The DNA code in most genes is expressed as a protein, which is a peptide made of the building blocks of individual amino acids. Each amino acid is coded for by a sequence of three DNA bases, known as a codon. For some amino acids, there is more than one codon (Table 8.1). A long series of DNA codons in a gene will thus code for an entire protein. The mRNA codons coding for amino acids are identical to DNA codons, with the substitution of uracil (U) for thymine (T). There is a tightly controlled mechanism for the generation of protein from a DNA template.

To decode a gene into protein, the DNA is first transcribed into mRNA. A strand (the 'sense' strand) of the DNA double helix is used by the enzyme RNA polymerase to synthesise a complementary strand of mRNA. Transcription of mRNA starts from the 5' end of the first exon of the gene, until the end of the most 3' exon. The intervening introns are initially included, and the first molecule is known as pre-mRNA. The intronic RNA sequences are spliced out

and a 3' polyadenine tail is added, producing mature mRNA. The mature mRNA is then transferred from the nucleus to the ribosome, to be used as a template for the production of protein. The mature mRNA has both 5' and 3' untranslated regions.

Protein synthesis does not begin at the 5' end of the mRNA, but at the first 5' AUG codon, which codes for the amino acid methionine. Protein translation stops at the first truncation codon (usually UGA) thereafter (see Fig. 8.3). In the ribosome, amino acid-specific transfer molecules, called transfer RNAs (tRNAs), bind a free molecule of their specific amino acid. The binding is carried out by an anticodon in the tRNA, which is complementary to the mRNA that codes for that specific amino acid. Using its anticodon, the tRNA binds the specific mRNA codon for its amino acid. By a complex machinery, the amino acid is then added to a growing peptide chain which will eventually form the mature protein (Fig. 8.4). The 5' end of the mRNA corresponds to the NH₂ (amino terminus) of the protein, and the 3' end of the mRNA corresponds to the COOH (carboxyl terminus) of the protein. Many proteins in higher species are modified after translation by the addition of phosphate or lipid groups.

Chromosomes and cell division

The first coiling of DNA is in the form of the double helix. However, there are subsequent higher orders of coiling and packaging of DNA. The first order gives a loop of about 146 bp in size, wound around a histone protein. The complex is known as a nucleosome. The highest order of coiling of a large DNA molecule, with its associated histones and other proteins, is known as a chromosome.

A chromosome consists of one very long double helix of DNA, containing very many genes in millions of basepairs. Humans are diploid; that is, they have two copies of every chromosome. The normal human chromosome complement is 46, made up of 22 pairs of autosomes (non-sex chromosomes) and two sex chromosomes, either X and Y in a male, or X and X in a female. Each member of a pair of autosomes contains the same genetic

information. The pair of X chromosomes in a female will contain the same genetic information, but the X and Y chromosomes in a male only have a small number of genes in common. A normal human metaphase karyotype is shown in Figure 8.5.

When cells divide, the genetic content must also be duplicated so that the daughter cells have the correct genetic material. Most cell division occurs as mitosis, where one cell divides to give two

genetically identical cells. This is the process which allows the formation of a complete human being from one fertilised embryo, and is also the process by which the cells of many organs are constantly renewed. Mitosis is one short period during a carefully programmed cell cycle (Fig. 8.6). After mitosis, the cell may enter a resting phase (G₀), or go on to divide again (G₁). A cell in G₁ will then go on to synthesise new DNA as described above (S phase). There is then a second gap phase (G₂), followed by mitosis (M).

Prior to mitosis, the cell can be said to be in interphase, during which the chromosomes are very elongated. Just before mitosis, in S phase, the chromosomes are duplicated and begin to condense as two (sister) chromatids per chromosome. This condensation phase is known as prophase. In the next phase, metaphase, the condensed chromatids line up along the plane of the cell, and spindle fibres develop between the centromeres (narrow waist of each chromatid) and the polar centrioles. Standard analysis of human chromosomes is carried out in metaphase. The chromatids separate, starting from each centromere, and pass to the new daughter cell, in the step called anaphase. By the telophase, the chromatids have reached to opposite poles of the dividing cell, and division completes.

Meiosis is the form of division required to form gametes (sperm or oocyte). Gametes are haploid, with only one of each chromosome – 23 in the case of humans. This allows the formation of a new diploid organism from two haploid gametes. Meiosis occurs in

Fig. 8.4 Protein synthesis from mRNA.

Case: Unilabs Slide: male Cell: I Patient:

Fig. 8.5 A normal human metaphase karyotype.

Fig. 8.6 Cell cycle.

two stages, meiosis I and meiosis II. The first phase of meiosis I, prophase I, is similar to that in mitosis, with the appearance of two condensed chromatids which have duplicated. At this stage, crossing over of genetic material from one chromatid to another can occur. It is estimated that one or two crossovers occur per chromosome in each meiosis. This introduces further genetic diversity, ensuring that the inherited chromosomes are different from the chromosomes of the parent. Metaphase I then occurs, where chromatids do not separate but go to the opposite ends of the cell in anaphase I and telophase I. The cells at this stage are still diploid.

The second meiotic division then occurs, where chromatids condense again in prophase II, and line up along the axis of the dividing cell in metaphase II. The chromatids then separate, passing to opposite ends of the cell in anaphase II. The new cells are then haploid, with 23 chromosomes, and the chromatids elongate into thin strands in telophase II.

Chromosome analysis

To examine chromosomes from a patient (a karyotype), dividing cells in culture must be examined. These cells are usually lymphocytes, amniotic fluid cells or fibroblasts. Cells are arrested in the metaphase stage of mitosis, and stained in such a way that the chromosomes are easily visualised. The usual technique used is G-banding (using a Giemsa stain), which gives a characteristic positive and negative banding pattern to each chromosome. Each chromosome has a constriction, called a centromere, dividing the chromosome into a short arm (p) and a long arm (q). Each arm has a number of prominent bands, which can then be subdivided into smaller bands. The gene for the ABO blood group is localised to chromosome 9q34. The gene thus lies in the fourth subband from the centromere (q34) of the third band from the centromere (q34) on the long arm (q34) of chromosome 9 (9q34).

Chromosome abnormalities can be broadly classified into abnormalities of chromosome number or a rearrangement of a normal number of chromosomes. The critical issue in most cases for determining the significance of a chromosome abnormality is whether the abnormality gives rise to an excess or deficiency of the normal diploid state (aneuploidy).

Abnormalities of chromosome number are relatively common, but many are not recognised as they may result in the early loss of a pregnancy. Triploidy (69 chromosomes) and tetraploidy (92 chromosomes) are relatively common causes of early pregnancy loss. Trisomy, the presence of a single extra chromosome (47

Fig. 8.7 Different types of chromosome anomaly. A–D represent notional chromosomal loci.

chromosomes), is also a common cause of miscarriage. Specific trisomies can give rise to an affected neonate, the commonest being trisomy 21 (Down syndrome), trisomy 13 (Patau syndrome) and trisomy 18 (Edward syndrome). All these trisomies usually occur as a result of autosomal non-dysjunction in meiotic division of the oocyte. In non-dysjunction, the specific chromatids fail to separate, resulting in an extra chromosome in one oocyte and no chromosome in the opposite gamete. A fertilised embryo from the oocyte with an extra chromosome will therefore be trisomic. The fertilised oocyte with an absent chromosome will be monosomic, and be lost as an early miscarriage. Non-dysjunction tends to occur more frequently with increasing maternal age. Non-dysjunction can occur in the male germline, but rarely produces viable offspring.

There are numerous types of chromosome rearrangements, the commonest of which are shown in Figure 8.7. Pericentric and paracentric chromosome inversions are usually balanced, and inherited without any phenotypic effect. Paracentric inversions are usually associated with a low risk of producing a liveborn unbalanced karyotype, but pericentric inversions may carry a higher risk. Insertions, duplications, deletions, isochromosomes and ring chromosomes are all usually aneuploid and associated with significant clinical abnormalities. Reciprocal translocations occur where there is exchange of genetic material from one arm of a chromosome in return for genetic material from a different chromosome. Reciprocal translocations are usually balanced, without any clinical effect, but may carry a risk of having a child with problems due to an unbalanced karyotype.

Another type of translocation is between the acrocentric chromosomes (13–15, 21 and 22), where there is no appreciable coding material on a very small short (p) arm. This is known as a Robertsonian translocation. Robertsonian translocations are one of the commonest human chromosome translocations, and in the balanced form have no clinical effect. A Robertsonian translocation involving chromosomes 14 and 21 is shown in Figure 8.8. Those who carry a Robertsonian translocation involving chromosome 21 may be at significantly higher risk of having a child with Down syndrome as an unbalanced product of the translocation. The same applies to a lesser extent for those carrying a Robertsonian translocation involving chromosome 13, and a subsequent risk of a child with Patau syndrome.

The nomenclature for reporting a chromosome analysis is strict, and needs to be read carefully. A karyotype is reported initially as the number of chromosomes, regardless of whether or not those chromosomes are normal. The sex chromosomes are then described. If there is no further abnormality, the report is then complete. Any

Fig. 8.8 Robertsonian translocation.

further abnormality is added after the sex chromosomes. A normal male karyotype is thus 46,XY. A male with non-dysfunctional Down syndrome will have the karyotype 47,XY,+21, an extra unattached chromosome 21. A male with Down syndrome due to a Robertsonian translocation between chromosomes 14 and 21 will have the karyotype 46,XY,t(14;21), and his carrier mother will have a karyotype 45,XX,t(14;21).

A standard laboratory chromosome analysis will be performed on G-banded chromosomes, which will detect many common and less common chromosome abnormalities, and in most cases no further laboratory work is required. However, recombinant DNA technology has allowed new techniques for chromosome analysis, based on the hybridisation of fluorescently labelled fragments of DNA to the DNA of chromosomes, prepared in a standard fashion, immobilised on a glass slide. The slides can then be visualised by eye using a fluorescent microscope, or indirectly by generating an image of the hybridisation on computer. This technique is known as fluorescent in situ hybridisation (FISH). The information that can be gained from this technique depends on the origin of the fragments of DNA hybridised to the chromosome preparation. Labelled whole chromosome 'paints', consisting of DNA exclusively from one chromosome, are now commercially available. For example, whole chromosome paints can be used to identify the origin of extra chromosomal material which cannot be identified using G-banding techniques. Whole chromosome paints are also helpful in determining the origin of subtle complex translocations. It is also now technically possible to use a chromosome 21 paint on uncultured cells in interphase, to look for trisomy 21. A cell would show three fluorescent nuclear dots, representing three chromosomes 21, as opposed to two in the normal situation.

Fluorescently labelled small DNA fragments, corresponding to 40–50 kb of DNA from a specific chromosomal region, can also be hybridised to metaphase chromosomes. Chromosomal deletions which cannot be detected within the resolution of conventional cytogenetic analysis can be detected by this FISH method. A normal karyotype will give two hybridisation signals, one from the same part of each chromosome. A karyotype containing a submicroscopic chromosomal deletion involving the segment of the chromosome corresponding to the 50-kb DNA fragment will give only one hybridisation signal. An example would be the submicroscopic deletion of chromosome 22q11 which occurs in most cases of the Di George spectrum (see Chapter 31), which can only be seen by FISH analysis (Fig. 8.9). FISH diagnosis of submicroscopic chromosomal deletions is likely to become available for a variety of specific clinical syndromes.

Fig. 8.9 (a) Ideogram of chromosome 22, indicating the region of 22q11.2 deleted in Di George syndrome. (b) Fluorescent in situ hybridisation (FISH) study of metaphase chromosomes from a patient with a microdeletion of chromosome 22q11.2. The normal chromosome 22 on the left (arrow) shows red signal from a FISH probe for the critical region of 22q11.2 and green signal from a control probe for the telomeric region of 22q13.3. The deleted chromosome 22 is shown on the right (arrow), with only the green signal from the control 22q13.3 visible. No red signal is seen from the critical region FISH probe on the deleted chromosome 22, as the region of that chromosome 22 corresponding to the critical region 22q11.2 probe is absent. The 22q11.2 microdeletion, usually 3 megabases in size, is too small to be seen using conventional G-banded chromosome analysis.

Fig. 8.10 Autosomal dominant inheritance. Note male-to-male transmission and non-penetrance in II:4.

Fig. 8.11 Autosomal recessive inheritance.

Patterns of inheritance

Single gene disorders have one of three principal modes of inheritance: autosomal dominant (AD), autosomal recessive (AR) and X-linked recessive (XLR). Other rare forms of inheritance include X-linked dominant (XLD) and mitochondrial disorders, as well as disorders due to abnormalities of genetic imprinting. Disorders caused by inheritance of unstable elements of DNA are now increasingly being recognised (see below).

Autosomal dominant inheritance

AD disorders are characterised by vertical transmission from parent to child, and the hallmark of these conditions is male-to-male transmission of the disease (Fig. 8.10).

Those affected with an AD disorder have a fault in one or other copy of the two genes responsible for that condition. Each child of a person with an AD disorder has a 50:50 chance of inheriting the gene responsible for the condition from its parent. There are many examples of AD disorders, including neurofibromatosis 1 and 2, familial adenomatous polyposis coli, myotonic dystrophy and Huntington disease. There can often be variability in both expression and penetrance of AD disorders. For example, neurofibromatosis 1, an AD condition, will almost always manifest in someone who has a neurofibromatosis 1 gene fault. This means that the condition has almost complete penetrance. However, different people can manifest the condition in different ways, some showing mild skin lesions and others showing severe intracerebral complications. This means that the expression of the condition is very variable. In contrast, only 80% of those who have a single gene fault for the rare hereditary form of retinoblastoma will actually develop an eye tumour. The penetrance in this situation is 80%, but the expression of the gene fault is consistent, as manifested by a retinoblastoma.

AD disorders are not commonly seen in neonatal practice. A list of the more frequent conditions is outlined in Table 8.2.

Autosomal recessive inheritance

When a child is diagnosed with an AR disorder, then both copies of a particular gene responsible for the condition are faulty. Both the child's parents are therefore carriers for that condition, with one normal and one faulty gene. Two of the child's four grandparents are also carriers, and it is likely that many of the child's relatives are also unknowingly carriers (Fig. 8.11). In most cases, being a carrier for an AR condition has no effect on that person. When both parents are carriers for a fault in the same gene, then there is a 25% chance of each of their children being affected by the condition.

Table 8.2 Autosomal dominant disorders in neonatal practice

SYSTEM AFFECTED	CONDITION
Neurological	Congenital myotonic dystrophy Neurofibromatosis type 1
Ocular	Congenital cataract Retinoblastoma
Haematological	Spherocytosis
Skeletal	Stickler syndrome Craniosynostosis syndromes Achondroplasia Osteogenesis imperfecta
Other	Beckwith–Wiedemann syndrome Noonan syndrome

The risk of a healthy carrier sibling having a child with the same condition depends on the chances of that sibling's partner also being a carrier. A child of a person with an AR disorder will automatically be a carrier. The child's chances of being affected will depend upon whether the child's unaffected parent is a carrier for a fault in the same gene.

AR disorders are commonly encountered in neonatal practice, and the nature of the disorder depends on the population being seen. Each regional population has its own recessive disorder, where the frequency of carriers for that disorder is highest. For instance, cystic fibrosis (CF) is a very common AR disorder in western Europe, whereas sickle-cell anaemia is the commonest AR disorder in West Africa. Common examples of AR conditions include CF, sickle-cell anaemia, several of the mucopolysaccharidoses, beta-thalassaemia, spinal muscular atrophy and congenital adrenal hyperplasia (Table 8.3). Prenatal diagnosis is available for many of these conditions.

X-linked recessive inheritance

In XLR inheritance, the condition affects almost exclusively males; females can be carriers (Fig. 8.12). The classic examples of such conditions are haemophilia A and B, Duchenne's and Becker's muscular dystrophy and Hunter syndrome.

The daughters of a man with an XLR condition are all obligate carriers. The sons of a man with an XLR condition are all normal, as they inherit his Y chromosome and not his X chromosome. When a woman is a carrier of an X-linked condition, each of her

Fig. 8.12 X-linked recessive inheritance.

sons has a 50 : 50 chance of being affected and each of her daughters has a 50 : 50 chance of being a carrier. There can be a relatively high mutation rate for some XLR conditions, and affected boys may not have a family history of the condition. About one-third of occurrences of Duchenne's muscular dystrophy are as a result of new mutations. Prenatal diagnosis is available for a wide range of XLR diseases. The more common X-linked disorders in neonatal practice are shown in Table 8.4.

Polygenic inheritance

Many congenital conditions do not have a clear mode of inheritance and can be classed as polygenic or oligogenic, where a disease may arise as a result of the effects of several genes. A good example is cleft lip and palate, which usually occurs in the absence of a family history. However, monozygotic twins have a high concordance for cleft palate, suggesting a genetic influence.

Other forms of inheritance

There are also much rarer forms of inheritance, including XLD, which can be hard to distinguish from AD, except that females will

be more mildly affected and there is no male-to-male transmission. An example of an XLD condition is hypophosphataemic rickets.

Mitochondrially inherited diseases show a very unusual pattern of inheritance. Most of the proteins in the mitochondria are encoded for by nuclear genes, but the mitochondria also contain their own small genome of 18 kb, with many copies per cell. The mitochondrial genome replicates independently and far more frequently than the nuclear genome. Several important mitochondrial proteins are encoded by the mitochondrial genome. Mitochondria are only inherited via oocytes, and not sperm. Therefore, when a gene fault is in the mitochondrial genome it will pass exclusively down the female line, but both males and females can be affected. The children of an affected male will not inherit his mitochondrial gene fault. Children with mitochondrial disorders can present with many varied symptoms, including myoclonic seizures, acute acidoses, muscle weakness, deafness or diabetes. A number of mutations or deletions in the mitochondrial genome have been described in patients with a wide variety of conditions, including myoclonic epilepsy with lactic acidosis and stroke-like episodes (MELAS) and myoclonic epilepsy with ragged red fibres on muscle biopsy (MERRF). To complicate matters further, Leber's hereditary ophthalmopathy is a mitochondrially inherited condition with a characteristic mitochondrial mutation, but the expression appears to have an XLR influence.

Some conditions show a phenomenon known as genetic imprinting. An imprinted gene has been marked during meiosis, to indicate the parent from whom it comes. For some genes it appears to be important not only to inherit two copies of that gene, but also to inherit one from each parent. Some genes may be silenced, depending upon which parent has passed on that gene. A good example is the presence of a small deletion of chromosome 15q, which has a different effect depending upon which chromosome 15 is deleted. If the deletion occurs on the chromosome inherited from a child's normal father, the child will develop Prader–Willi syndrome. If the deletion occurs on the chromosome inherited from a child's normal mother, the child will develop a completely different clinical condition, Angelman syndrome. The genes in this area of chromosome 15 are therefore imprinted. In addition, if a child has two maternal copies of chromosome 15 (maternal disomy), but no paternal copy, he or she will also develop Prader–Willi syndrome. Other

conditions that show imprinting effects include Russell–Silver syndrome, Beckwith–Wiedemann syndrome and the rare condition of transient neonatal diabetes mellitus.

A new molecular mechanism for genetic disease has been described – that of inherited unstable triplet repeat expansions. At least nine different conditions are caused by this phenomenon. In one of these conditions, a normal person has a stable number of a repetitive element of three bases of DNA (for example, 20 copies of a CAG repeat) in a particular gene, that gene functions normally, and the children of that person have the same number of repeats in their gene. An affected person has an increased number of repeats (say 100 copies) in that gene, and the affected children of that person have more serious disease, with perhaps 200 repeats in the gene. The molecular genetic findings appear to be the genetic correlate of the phenomenon of anticipation, where a condition appears to worsen from generation to generation. The most extreme example is that of congenital myotonic dystrophy, where a minimally affected mother can have a profoundly affected infant. In this case, there is a small repeat expansion of, say, 150 repeats in the mother, increasing to many hundreds of repeats in her affected infant.

This molecular mechanism is responsible for fragile X syndrome, Huntington disease, Friedreich's ataxia, several forms of spinocerebellar ataxia, and probably several more conditions.

Molecular genetic analysis for single gene disorders

Laboratory tests for single gene disorders have been available for a considerable time. Haemoglobin electrophoresis for sickle-cell anaemia and thalassaemia, and enzyme assays for Tay–Sachs disease, are very effective in resolving clinical issues in individual families. However, an increasing number of specific DNA-based tests can now be used in the diagnosis and prediction of single gene disorders.

The two major techniques used in molecular genetic analysis are the polymerase chain reaction (PCR) and Southern blotting. PCR is a technique which allows amplification of a specific genetic region in large quantities from a small amount of DNA template (Fig. 8.13). The DNA sequence of the region to be amplified must be known, so that synthetic pieces of single-stranded DNA (oligonucleotide primers) corresponding to the region can be designed and manufactured. The oligonucleotide primers are added in great excess to the DNA template, along with a thermostable DNA polymerase, and free nucleotides (A, C, T, G). The mixture is heated up to cause the two strands of template DNA to separate, and then cooled. As the DNA cools, the oligonucleotides bind to the template sequence and are extended by the polymerase. A new copy of the template DNA is thus produced. The cycle is repeated 30–40 times, with an exponential increase in the amount of the target sequence.

DNA generated by PCR can be used in many different ways to detect an abnormality in the sequence. If a known genetic abnormality is being sought, then specific PCR assays for mutations have been developed, such as the amplification-resistant mutation system (ARMS) test or the use of a specific DNA restriction enzyme which recognises a known mutant DNA sequence. In searching for an unknown mutation in a PCR product, the PCR-generated product is analysed on a semiautomated fluorescent DNA analyser, read up 600–700 basepairs of DNA sequence in the PCR product. If a pathogenic DNA mutation is found, then the test can help to confirm a clinical diagnosis.

Southern blotting is a more protracted procedure involving the digestion of a relatively large amount of DNA by a restriction

Fig. 8.13 Polymerase chain reaction.

enzyme. The digested DNA is then electrophoresed through an agarose gel, giving a smear of DNA of different sizes. The DNA is then transferred (blotted) and fixed to a membrane. The fixed DNA is then hybridised to a labelled DNA probe specific for the gene to be analysed, and the specific sizes of DNA to which the probe binds allows determination of the genotype (Fig. 8.14). This test is often superseded by PCR technology.

There are different degrees to which molecular genetic tests can contribute to clinical diagnosis. Some specific molecular genetic tests can be used to detect a known pathogenic DNA mutation and give a diagnosis, even without any knowledge of the patient's clinical status. For instance, the PCR detection of the F508del deletion in both copies of a person's CF (*CFTR*) gene immediately gives a diagnosis of CF. Such direct mutation tests are possible when both the gene responsible for a condition has been isolated and specific pathogenic mutations have been identified. Similarly, a PCR test detects a deletion of exons 7 and 8 in both alleles of a gene called *SMN* on chromosome 5q in almost all children with spinal muscular atrophy. Southern blot analysis of DNA from infants with congenital myotonic dystrophy shows a very large expansion in a triplet repeat DNA sequence in the myotonin kinase gene on chromosome 19, as described earlier.

In other cases, molecular genetic diagnosis can point towards a diagnosis without confirming it. For instance, the presence of a single F508del *CFTR* gene mutation in a child with a history suggestive of CF increases the likelihood of that child being affected.

Fig. 8.14 Southern blotting and hybridisation.

Fig. 8.15 Linkage analysis in an autosomal recessive disorder, using an intragenic polymorphic marker. Alleles 2 and 3 are associated with a gene mutation and can be used to predict the status of another sibling.

In some cases, where either a gene is not known or very few gene mutations have been identified in a known gene, gene-tracking studies can be performed in a family to predict whether a person in that family is affected. This is known as linkage analysis. Such a study requires careful clinical examination of several family members, to establish whether they are affected or unaffected. When their clinical status is clear, DNA samples are then obtained.

Gene-tracking analysis in the family uses the property of normal variations in a gene between different people. Some genetic areas show wide variation between individuals, and a DNA marker from such an area, which can detect many variations, is described as being polymorphic. Each variant of a polymorphic marker is known as an allele. There are now thousands of polymorphic markers covering most of the human genome, and such markers can be found very close to most known genes. There are several types of polymorphic DNA markers, including those characterised by different numbers of specific DNA-cutting enzyme recognition sites, or restriction fragment length polymorphisms. Other markers detect the variation in number of anonymous elements of repetitive DNA, and are called microsatellites or minisatellites.

If the two alleles of a polymorphic marker can be distinguished, to discriminate between the two copies of that particular chromosome from where the marker comes, then the marker is informative in that individual. When a gene location is known, but the actual gene has yet to be found, the alleles of informative markers lying either side of the gene will be inherited along with each copy of the gene in question. This can be used to predict a child's clinical status.

If one set of alleles is found in the affected members of the family but not in the unaffected, then the presence or absence of these alleles in the at-risk individual can be used to predict their chances of being affected. An example of linkage analysis for an AR disorder is shown in Figure 8.15. This form of linkage analysis is often used

in families with XLR conditions such as Duchenne's muscular dystrophy, to predict whether a woman is a carrier. Such linkage analysis can also be used in prenatal diagnosis.

Because of its nature, linkage analysis is more prone to error than is direct mutation testing. This can be due to difficulties in assessing a person's clinical status, and because of the possibility of recombination between the polymorphic markers. However, with the rapid advances in molecular genetics, many more mutations are being found in many different genes, and linkage analysis is often superseded by direct mutation testing.

New diagnostic genetic technology

There are two new forms of genetic analysis which are being introduced into widespread clinical practice in the next 3–5 years.

Genomic arrays

A new technological development is the ability to immobilise thousands and, more recently, millions of distinct recognisable pieces of DNA on slides of silicone or glass as ordered microarrays, colloquially known as DNA microchips. This genomic array technology can permit analysis of thousands of individual loci simultaneously, and gives chromosome analysis at a resolution at least 100 times greater than conventional G-banded chromosome analysis. Genomic array technology will identify pathogenic chromosomal anomalies in 20–25% of infants in whom no underlying diagnosis had been identified previously. There is a drawback, in that genomic array technology will often find genetic variants of unknown significance, and the current understanding of the role of such variants in disease pathogenesis is limited.

Next generation DNA sequencing

Present DNA sequencing technology allows analysis of several thousand DNA bases over a period of weeks. New short oligonucleotide DNA sequencing technology, called collectively next generation sequencing, can now permit the analysis of millions of DNA bases over a much shorter period of time. With this technology many genes can be analysed in a short clinically relevant period of time at reasonable cost. Thus in children with specific sets of malformations, direct sequencing of multiple genes in a short period of time will soon be available to provide rapid clinical information for clinicians and families.

Glossary

3' distal end of a gene, as indicated by the bond at the third hydroxyl group of the deoxyribose sugar

5' proximal end of a gene, as indicated by the bond at the fifth hydroxyl group of the deoxyribose sugar

acrocentric a chromosome with effectively only a long arm – chromosomes 13, 14, 15, 21 and 22

allele a genetic variation of a gene or DNA marker

aneuploidy an excess or deficiency of chromosomal material

anticodon an element of transfer RNA which binds a specific amino acid

autosomal dominant inheritance pattern characterised by transmission through several generations, male-to-male transmission and a 50:50 risk to the children of an affected person

autosomal recessive inheritance pattern characterised by several affected members of the same generation, with carrier parents and a 1:4 recurrence risk where both parents are carriers

basepair unit of double-stranded DNA

centromere element of chromosome involved in chromosome replication, found as a constriction in the chromosome

chromatid condensed chromosome found just before mitosis

codon 3-bp element of DNA encoding an amino acid

diploid a complement of two copies of each chromosome per cell

DNA marker a piece of DNA corresponding to a specific gene or chromosomal segment

enhancers elements of DNA which are involved in increasing gene transcription

exon a part of a gene which is transcribed into mRNA

expression the way in which a gene fault manifests clinically

FISH fluorescent in situ hybridisation, a powerful technique for studying specific chromosomes or regions of chromosomes

gamete a germ cell – sperm or oocyte

genetic imprinting the marking of a gene according to which parent has passed that gene to the child

haploid a complement of one copy of each chromosome per cell (as in sperm or oocyte)

haplotype a pattern of alleles of DNA markers representing one of the two copies of a chromosomal region

histone a DNA-binding protein important in chromosomal folding

interphase phase of mitosis in which the chromosomes are very elongated

intron the part of a gene between the exons which is not transcribed into mRNA

isochromosome an abnormal chromosome made up of two long or two short arms of a normal chromosome

karyotype an analysis of the chromosome complement of a cell type

linkage analysis the use of polymorphic DNA markers to perform gene-tracking studies within a family

meiosis the process of cell division to give haploid germ cells

metaphase phase of mitosis in which the chromosomes are very condensed and easier to analyse

microsatellite marker a DNA marker which detects variation in number of an anonymous small repetitive element of DNA

minisatellite marker a DNA marker which detects variation in number of an anonymous medium repetitive element of DNA

mitosis the normal process of cell division to give two diploid copies of a cell

non-dysjunction a failure of meiosis, giving two copies of a chromosome in one gamete and no copy of a chromosome in the other gamete

nucleosome the combination of a histone and its bound DNA

oligonucleotide primers small lengths of synthetic single-stranded DNA of a specific sequence

paracentric inversion a rearrangement of chromosomal material within one arm of a chromosome

PCR polymerase chain reaction: a method of generating large amounts of specific DNA from a small amount of target sequence

penetrance the number of people known to carry a gene mutation who manifest the condition

pericentric inversion a rearrangement of chromosomal material around the centromere of a chromosome

promoter element of a gene which is necessary to activate gene transcription

prophase phase of the cell cycle where condensation of the chromosomes occurs, just before metaphase

reciprocal translocation exchange of chromosomal segments between different chromosomes

restriction enzyme an enzyme which cuts double-stranded DNA at a specific unique short DNA sequence

restriction fragment length

polymorphism a genetic variation between two copies of the same gene, where one gene may have one copy of a restriction enzyme recognition site, and the other two. This variation can be detected using PCR or Southern blotting

ribosome area of the cell where mRNA is converted into protein

ring chromosome an abnormal chromosome where the tips of the long and short arms have fused

Robertsonian translocation a fusion of two acrocentric chromosomes

Southern blotting a process of immobilising DNA to nylon membrane for genetic analysis

suppressor a DNA element which reduces the expression of a gene

telomere the end of a chromosome

telophase the last phase of mitosis

transcription the process of converting DNA into mRNA

translation the production of protein from a DNA sequence

triploidy three of each chromosome, i.e. 69 chromosomes in humans

trisomy one extra chromosome, i.e. 47 chromosomes in humans

X-linked recessive inheritance characterized by affected males in several generations, and by female carriers

Introduction

The field of prenatal diagnosis and fetal medicine continues to advance at a rapid pace. Improved ultrasound imaging has enhanced the detection of fetal anomaly, and the use of other modalities, such as magnetic resonance imaging (MRI), has allowed further detailed assessment, especially of the central nervous system (CNS).

The drive for early detection of pregnancies at increased risk of aneuploidy continues, with first-trimester combined biochemical and ultrasound assessment now generally available. Molecular technologies continue to be refined, with the most notable advance being the accurate identification of free fetal deoxyribonucleic acid (DNA/RNA) in the maternal circulation, allowing non-invasive determination of fetal rhesus (Rh) status and the potential for genetic diagnoses.

The shift away from invasive procedures to assess fetal well-being continues. Fetal anaemia now is recognised by alterations in middle cerebral artery (MCA) blood flow velocity, and analysis of both the arterial and venous sides of the circulation allows improved accuracy of optimal timing of delivery in cases of fetal growth restriction (FGR).

The complications of monochorionic twin pregnancies contribute significantly to the workload of a modern fetal medicine unit. The dilemmas in management in cases of discordant fetal anomaly, and the transfusional complications, including twin-to-twin transfusion syndrome (TTTS), have led to the development of several techniques that enable the relatively safe occlusion of interfetal blood flow.

Fetal surgery continues to be developed. Most units have shifted their emphasis away from open techniques, where maternal complications are common, to endoscopic procedures, with most attention currently being directed towards the repair of neural tube defects (NTDs) and congenital diaphragmatic hernia (fetoscopic endotracheal occlusion (FETO) procedure).

Fetal physiology

Our understanding of fetal physiology has for years been based on indirect sources. Observations in preterm neonates were first assumed to apply to the fetus of comparable gestation, and then extrapolated back to the mid-trimester. Non-invasive techniques such as cardiotocography (CTG), ultrasound and Doppler have provided information on fetal circulation, growth and behaviour. Amniotic fluid, being largely dependent on fetal urination, has been the traditional source for information about fetal biochemistry and endocrinology (Dallaire and Portier 1986). Access to the fetal circulation in the 1980s allowed fetal haematology and biochemistry

to be evaluated directly in utero. Knowledge of normal values in the mid-trimester fetus is essential in the prenatal diagnosis of several fetal diseases and forms the basis for more effective treatment of maternal alloimmunisation and better management of growth retardation, and is a prerequisite for other diagnostic and therapeutic approaches in the fetus. The main topics of clinical interest are summarised below, although more detailed listings are available elsewhere (Rodeck and Nicolini 1988).

Haematology

Haemoglobin (Hb), packed cell volume (PCV) and red cell mass increase, while mean corpuscular volume (MCV), reticulocytes and nucleated red blood cells (RBCs) decrease significantly with gestation (Millar et al. 1985; Forestier et al. 1986), reflecting the increase in fetal haemopoietic tissue, and the progressive change from hepatic to myeloid erythropoiesis. The normal range for Hb increases from 9–13 g/dl at 17 weeks to 13–18 g/dl at term (Nicolaides et al. 1988b), as does haematocrit, from 29–42% at 18 weeks to 35–48% at 30 weeks (Forestier et al. 1986). The myeloid series does not change with gestation, nor do platelets, which normally exceed $150 \times 10^9/l$. Normal ranges are available for coagulation factors, which are reduced compared with the adult (Mibashan and Rodeck 1984).

Acid-base balance

In normal pregnancies, pH changes with gestational age, and ranges in the umbilical vein from 7.32 to 7.44. On the other hand, PO_2 decreases with gestational age, whereas PCO_2 and bicarbonate rise. The decrease in fetal PO_2 is compensated for by the rise in fetal Hb, so that total oxygen content remains unchanged at 6–7 mmol/l. Normal ranges have been established for both umbilical venous and arterial samples (Fig. 9.1) (Nicolaides et al. 1989).

Cardiovascular physiology

Mean umbilical venous pressure is 4–5 mmHg between 20 and 33 weeks' gestation (Nicolini et al. 1989e). Blood volume has been measured in vivo, on the basis of the change in fetal haematocrit produced by transfusion of a known quantity of red cells. Fetoplacental blood volume rises from 25 ml at 18 weeks to 150 ml at 31 weeks, but during the same interval it decreases when expressed as a function of fetal weight, from 117 to 93 ml/kg (Nicolaides et al. 1987b).

Biochemistry

Reference ranges are available for electrolytes and biochemical indices of renal, hepatic and bone function (Moniz et al. 1985; Forestier et al. 1987). Fetal sodium and potassium are the same as maternal levels. Fetal glucose levels are lower than in the mother, and their maternofetal gradients have been used as an index of placental transfer (Nicolini et al. 1989b). Bilirubin is three times higher in the mid-trimester fetus than in the mother, but albumin levels are considerably lower, with values rising from 16 g/l at 15 weeks to 40 g/l at term (Moniz et al. 1985).

Renal function

Urea and creatinine levels in utero reflect the excretory function of the placenta and not that of the kidneys. Urinary sodium and phosphate decrease and creatinine increases with gestational age, consistent with progressive maturation of tubular function and an

Fig. 9.1 Reference range (mean and 95% data intervals) for PO_2 in umbilical venous and arterial blood throughout gestation. (Reproduced from Nicolaidis et al. (1989).)

increase in glomerular filtration rate. Potassium and urea, however, do not change, suggesting that the changes in tubular reabsorption occur simultaneously with those in tubular secretion and glomerular filtration. Reference ranges related to gestation are used in the assessment of renal function in fetuses with obstructive uropathies (Nicolini et al. 1992).

Fetal pain

This is a complex area but is of importance with the increasing number of in utero (and often in fetu) interventions being developed in the field of fetal medicine/surgery. It is clear that the fetus mounts a stress response to painful stimuli from 18 weeks (Giannakouloupoulos et al. 1994, 1999; Teixeira et al. 1996, 1999), but whether this is perceived as pain is uncertain. Neurons first link the cortex with the rest of the brain at 16 weeks, and their activation might be associated with an unpleasant experience, if not pain itself. By 26 weeks, the system for nociception is present and functioning (Kostovic and Rakic 1990) and it seems likely that the fetus can feel pain from this stage. This evidence leads to the consideration of fetal analgesia for invasive procedures during the second and third trimesters. However, the challenge remains selecting the safest and most effective type and route of analgesic drug without increasing maternal or fetal risks.

Antenatal diagnosis

Ultrasound

Ultrasound is the chief method for detecting structural abnormalities. Since the first report of detection of a fetal anomaly leading to termination of pregnancy (Campbell et al. 1972), a wide range of major malformations have been detected. With advances in ultrasound imaging, the appearances of an increasing number of minor malformations have now been described.

The standard of ultrasound achieved in practice has continued to improve dramatically and is available to an increasing proportion

of the population. Routine ultrasound screening is recommended in the UK (Royal College of Obstetricians and Gynaecologists 1984). This examination is delayed until 18–20 weeks, when cardiac and renal structure becomes discernible. Routine screening detects 60–80% of major and 35% of minor congenital malformations (Levi et al. 1989; Chitty et al. 1991; Luck 1992), in contrast to the 25% detected (Hegge et al. 1989) under the indication-based system favoured in the USA (National Institutes for Health 1984).

Only the main areas of ultrasound diagnoses are summarised below; exhaustive listings are available elsewhere (Reznikoff-Etievant 1988; Whittle and Connor 1994).

Neural tube defects (Ch. 40.8)

The diagnosis of anencephaly is straightforward: the cranial vault cannot be visualised in the standard view for biparietal diameter measurement. Detection of open myelomeningocele is more complex. Although larger defects may be suggested by gross disruption in vertebral integrity in the longitudinal plane or by soft-tissue signs, smaller defects will only be apparent in the horizontal planes of a few localised vertebrae, as subtle splaying in the lateral processes. These views can be difficult to obtain, especially if the fetal spine lies against the uterine wall, and in this context screening has been greatly facilitated by two cranial signs found in almost all fetuses with myelomeningocele. Scalping of the frontal bones gives the head a lemon-shaped appearance ('lemon' sign), whereas the normally dumbbell-shaped cerebellum appears either absent or banana-shaped ('banana' sign: Fig. 9.2) (Nicolaidis et al. 1986a; Furness et al. 1987; Pulu et al. 1988). The latter results from downward herniation of posterior fossa contents, and the former from the subsequent reduction in intracranial volume.

Ultrasound screening using the lemon and banana signs should theoretically detect 96–100% of myelomeningoceles (Campbell et al. 1987; Van den Hof et al. 1990). Ultrasound features such as head circumference greater than the 90th percentile and lesions at L3 and above have been demonstrated in multivariate analysis to be independently associated with lower rates of survival in children born with spina bifida (Van Der Vossen et al. 2009). In a

Fig. 9.2 (A) The normal dumbbell shape of the cerebellum (arrows) on ultrasound at 18 weeks. (B) Anterior curvature of the cerebellum, the 'banana' sign (arrows), in a fetus of similar gestation with open spina bifida.

long-term follow-up study of an unselected cohort of infants born with spina bifida between 1963 and 1971, by the mean age of 30 years the survival rate was approximately 50%. Only one-third of the survivors lived independently, with up to a third requiring daily care. Sensory levels recorded at infancy were correlated with rates of mortality and morbidity, with higher sensory levels associated with poorer outcome (Hunt and Oakeshott 2003; Oakeshott and Hunt 2003). See Chapter 40 part 8 for more information on neonatal aspects of spina bifida.

It is important to recognise that ultrasound is both a screening and a diagnostic test, and that small spinal lesions in fetuses with suspicious cranial signs on screening may only be detected on detailed scanning by a very experienced operator, and that the antenatal prediction of the level of the lesion may not always correspond to that found after birth. In cases of genuine uncertainty, an elevated amniotic fluid concentration of acetylcholinesterase may also be measured to confirm the presence of an open NTD (Loft et al. 1993).

Other craniospinal malformations

Ventriculomegaly is diagnosed in utero by elevated ratios of various measurements of the lateral ventricle to hemispheric width in the transverse plane (Fiske et al. 1981; Campbell and Pearce 1983) or enlargement of the atrium of the posterior horn of the lateral ventricle (Cardoza et al. 1988). Unless there is progressive or gross dilatation, caution should be exercised in the interpretation of mild ventriculomegaly, especially in the mid-trimester. In a recent review of the literature on isolated mild ventriculomegaly, defined as ventricular atrial width of 10.0–15.0 mm, there was no conclusive evidence that the width of the ventricular atria was associated with the risk of neurodevelopmental outcome (Melchiorre et al. 2009). The pooled incidence of neurodevelopmental delay in this review was 11%. Limitations in the current literature include evidence from small retrospective case series and lack of long-term follow-up studies. Important adverse prognostic indicators include progressive ventricular dilatation and other associated abnormalities.

The level of obstruction is determined by examining the third and fourth ventricles and the aqueduct of Sylvius. Hydranencephaly is distinguished from severe hydrocephalus by the absence of midline structures and the lack of a residual cortical rim, but the distinction may be difficult in extreme cases. In holoprosencephaly, the extent of midline ventricular fusion varies with the degree of failure of cleavage of the prosencephalon (Pilu et al. 1987), and there are often concomitant facial anomalies. The diagnosis of microcephaly should only be made in the presence of serial measurements of head circumference 3–4 standard deviations (SD) below the mean, so as to exclude growth retardation or incorrect dating. The ultrasonic appearances of encephalocele, and intracranial cysts, tumours and haemorrhage, are well described. Agenesis of the corpus callosum, increasingly recognised as separation of the lateral ventricles with upward displacement of the third ventricle, is more difficult to diagnose, and is often detected in association with other CNS abnormalities (Sandri et al. 1988).

The diagnosis of posterior fossa abnormalities, and most notably the Dandy–Walker malformation and its variants, is challenging. The classic appearance is of complete or partial agenesis of the cerebellar vermis with a posterior fossa cyst (Fig. 40.90). However, in one series from a tertiary unit in the UK, the correlation with postmortem was only 43% (6/14) for this abnormality (Carroll et al. 2000). This has led to evaluation of fetal MRI for complex neurological abnormalities (see below).

Cardiac defects

Following characterisation of the normal ultrasonic appearances of the fetal heart, a wide range of defects have been diagnosed. Inspection of the four-chamber view in a transverse plane during the routine 18-week scan detects approximately 20–40% of severe congenital heart disease (Fermont et al. 1985; Sharland and Allan 1992). This view is abnormal with major defects such as hypoplastic ventricles, atrioventricular canal defects and tricuspid atresia, although minor lesions such as septal defects may be missed. Visualisation of venoatrial and ventriculoarterial connections is

Fig. 9.3 Congenital cystic adenomatous malformation (CCAM) of the lung. A longitudinal view of a large macrocystic CCAM.

Fig. 9.4 The 'double-bubble' appearance of duodenal atresia.

more complex, but if it were introduced into routine screening it would theoretically increase the detection rate to greater than 80% (Stumpflen et al. 1996). Some cases are missed because of the evolution of the abnormality such that the heart may appear to be normal at the time of screening. The introduction of the five-chamber view, sagittal and parasagittal views has increased the detection rate of outflow tract anomalies (Allan 2004; Gardiner 2006; Jeanty et al. 2008).

Indications for fetal echocardiography include an abnormal four-chamber view or outflow tracts, an affected sibling or parental history, diabetes, exposure to cardiac teratogens, raised nuchal translucency (NT) measurement in a euploid fetus, and monochorionic twin gestations. A high degree of accuracy can then be achieved for diagnosis of major vessel lesions such as pulmonary stenosis, truncus arteriosus and transposition of the great vessels (Davis et al. 1990). Colour flow Doppler facilitates the demonstration of cardiac structure, and M-mode and pulsed-wave Doppler provide an index of cardiac function, which is particularly useful in arrhythmias.

Intrathoracic defects (for neonatal surgical management, see Ch. 29.4)

Most intrathoracic lesions identified prenatally are benign, but their significance is the association with pulmonary hypoplasia. Indirect indices of the severity of compression on the developing lung are the degree of mediastinal shift, the presence of polyhydramnios due to limited swallowing, and hydrops secondary to obstructed venous return. Left-sided diaphragmatic hernias are detected on ultrasound because of displacement of the heart to the right, fluid-filled bowel within the chest, and absence of the stomach intra-abdominally (Chinn et al. 1983; Nakayama et al. 1985). As herniated liver has the same echotexture as the lung, right-sided lesions are more difficult to detect, especially in the absence of polyhydramnios or pleural effusion. Clues include derangement in the normal intra-abdominal course of the gallbladder and intrahepatic vein, although small lesions may go undetected.

The appearances of congenital cystic adenomatoid malformation (CCAM) (now often termed congenital pulmonary airway malformation; Ch. 27.5) of the lung vary from solitary large cysts to solid echogenic lesions, with the worst prognosis (Fig. 9.3) (Adzick 1985a; Stocker et al. 1977; Adzick et al. 1985). The assessment of

prognosis is difficult, although in more recent series it appears good, other than in a small minority (6%), in which both mediastinal shift and hydrops are present (Roelofsen et al. 1994; Barrett et al. 1995). Some disappear, many get smaller, and only a few stay the same or progress. Diagnosis cannot always be certain antenatally, and differentiation between CCAM, sequestered lung, tracheal or bronchial atresia, and congenital diaphragmatic hernia may be difficult (McCullagh et al. 1994; King et al. 1995). Mediastinal teratomas have features on ultrasound similar to solid type III or microcystic CCAM lesions (Romero et al. 1982).

Gastrointestinal defects (for neonatal surgical management, see Ch. 29.4)

Oesophageal atresia can be diagnosed when polyhydramnios occurs with non-visualisation of the fetal stomach, although these signs may not be present in the common form associated with tracheo-oesophageal fistula (Farrant 1980). Duodenal atresia produces polyhydramnios and a characteristic 'double-bubble' appearance (Fig. 9.4), which may not be apparent until the third trimester (Nelson et al. 1982). Associated anomalies are common in the above two conditions, unlike in more distal obstructions. Small-bowel obstructions are more likely to be associated with increased amniotic fluid volume than are large-bowel obstructions such as anal atresia, which may go undetected in utero. Peristalsis may be seen (Arulkumaran et al. 1990) and bowel perforations may show up as ascites or, more commonly, hyperechogenicity from meconium peritonitis (Blumenthal et al. 1982). Caution must be exercised when gut echogenicity is detected as an isolated finding, as, although this may be associated with cystic fibrosis (Muller et al. 1985) and aneuploidy, the majority occur in normal fetuses (Fakhry et al. 1986). Meconium peritonitis can also produce pseudocysts, the differential diagnosis of which includes gastrointestinal duplications and choledochal, mesenteric and ovarian cysts.

The distinction of exomphalos from gastroschisis is crucial, given the high incidence of cardiac and chromosomal abnormalities in the former (Gilbert and Nicolaides 1987). Aneuploidy seems largely confined to fetuses in which the herniated liver is not present within the exomphalos (Nyberg et al. 1989; Benacerraf et al. 1990). More severe degrees of failure of fusion of the ectomesodermic folds, such as ectopia cordis, ectopia vesicae, pentalogy of Cantrell and the body stalk anomaly, are readily apparent. In contrast, gastroschisis

is rarely associated with aneuploidy or genetic conditions. Non-genetic associations include young maternal age, socioeconomic deprivation, ethnicity, maternal smoking, medication (aspirin, ibuprofen, paracetamol and decongestants), illicit drug use and maternal nutritional status (Rasmussen 2008). There are however trends in the incidence of gastroschisis which remain unexplained. These include the increasing incidence of gastroschisis in the UK and the clustered distribution of cases in the population (Tan *et al.* 1996; Penman *et al.* 1998). These patterns suggest a clustered exposure to one or more risk factors which are increasing over time (Rasmussen 2008).

Genitourinary defects (for neonatal diagnosis and management, see Ch. 35.2)

Renal and urinary tract abnormalities are common and comparatively easy to detect, largely because obstructive lesions manifest as cystic spaces, whereas those with poor urine output are characterised by oligohydramnios. Major anomalies such as renal agenesis or low obstructive uropathy will be detected on routine scan at 18–20 weeks, when urine output makes a major contribution to amniotic fluid volume, whereas more minor lesions, such as mild ureteropelvic junction obstruction, may not be obvious until later. As the lack of amniotic fluid in renal agenesis significantly impairs the ultrasound picture, it can be extremely difficult to demonstrate the absence of kidneys in the renal fossae. In these circumstances, referral for confirmation by transvaginal ultrasound and/or amniocentesis has been recommended (Fisk *et al.* 1991). However, colour flow Doppler imaging of the renal arteries may be adequate to provide the diagnosis: the absence of renal artery colour image confirms no functioning tissue (Sepulveda *et al.* 1995).

Multicystic kidneys are distinguished from hydronephrotic kidneys by their cystic spaces being more peripheral and variable in size, and their stroma more central (Fig. 9.5) (Beretsky *et al.* 1984). The cysts of infantile polycystic kidneys are too small to be resolved by ultrasound, but the kidneys appear enlarged with abnormal echogenicity, associated with oligohydramnios. Occasionally with later-onset infantile polycystic kidney disease the kidneys may appear normal in utero (Romero *et al.* 1984).

The significance of mild pelvicalyceal dilatation remains controversial. Studies show that progressive enlargement, or an anteroposterior diameter of >10 mm in the third trimester, is more likely to be associated with pathology (Ouzounian *et al.* 1996). The

ultrasound picture in low obstructive uropathy depends on the severity and duration of obstruction. The bladder is variably enlarged and thick-walled, and careful scanning reveals dilatation of the upper urethra in those with posterior urethral valves (PUVs) (Hobbins *et al.* 1984). Oligohydramnios, upper tract dilatation and hyperechogenic fetal kidneys may also be present.

Skeletal defects (for neonatal diagnosis and management, see Ch. 31, Ch. 34.4)

Isolated malformations detected on routine scanning include kyphoscoliosis, hemivertebrae, limb reduction and shortening, sacral agenesis, polydactyly and flexion deformities. Over 100 distinct skeletal dysplasias are amenable to prenatal diagnosis, both by serial measurement of long bones and by detection of abnormal skeletal shape or mineralisation. Although severe limb shortening, abnormal head or chest shape, or polyhydramnios may alert the sonologist to their presence, determination of the exact type of skeletal dysplasia is difficult in the absence of a previous history, and requires detailed evaluation of hands and feet, thoracic dimensions, face and cranium, and measurement of all the long bones, before consulting comprehensive tables of diagnostic features (Romero *et al.* 1988). Even then, diagnosis may only be made postnatally, when additional investigations such as skeletal X-ray are available. In achondrogenesis, thanatophoric and diastrophic dwarfism, severe limb reduction will be obvious by 18 weeks (Filly and Golbus 1982), whereas in the heterozygous form of achondroplasia this may not be observed until almost the third trimester (Filly *et al.* 1981). If achondroplasia is suspected, amniocentesis can be performed for DNA testing on fibroblasts to detect or exclude the fibroblast growth receptor 3 (FGR-3) mutation known to cause achondroplasia (Bonaventure *et al.* 1996). Abnormal bone shape is a feature of camptomelic and thanatophoric dysplasia, whereas fractures, callus formation and hypomineralisation may be seen in osteogenesis imperfecta types II–IV (Brons *et al.* 1988). Hypomineralisation is also seen in hypophosphatasia and achondrogenesis. Radial aplasia may be associated with trisomy 18, but also with rare genetic syndromes such as Fanconi's anaemia and the thrombocytopenia-absent radius syndrome.

Soft-tissue abnormalities

Cleft lip, whether isolated or associated with cleft palate, can be detected by imaging the fetal face in coronal and transverse views (Salvodelli *et al.* 1982). Rarer midline clefts are often accompanied by other midline defects, such as holoprosencephaly, ethmocephaly or proboscis. The diagnosis of isolated cleft palate is extremely difficult prenatally (Pilu *et al.* 1986). These lesions are usually only detected on detailed scans of patients who have either other abnormalities or an at-risk history. Isolated unilateral clefts are rarely associated with either aneuploidy or genetic syndromes; however, these risks increase with bilateral clefts and the presence of associated anomalies.

Cystic hygromas are readily apparent as multiseptate thin-walled cystic lesions, found most commonly around the dorsolateral region of the neck (Chervenak *et al.* 1983). As they result from obstruction of the jugulolymphatic channels (Andres and Brace 1990), hygromas frequently progress in utero to hydrops and fetal demise (Abramowicz *et al.* 1989), although spontaneous resolution is possible (Chodirker *et al.* 1988). They have a strong association with aneuploidy (50–80%), and therefore karyotyping is advised. Hydrops is obvious as generalised skin oedema with ascites, and in many cases there will also be pericardial and pleural effusions, placentomegaly and polyhydramnios.

Fig. 9.6 Three-dimensional ultrasound of the face of a fetus with known cardiac abnormality and oesophageal atresia. No dysmorphic facial features were confirmed.

Other imaging modalities

3D/4D ultrasound

The use of three-dimensional (3D) ultrasound in prenatal diagnosis has increased in recent years with the development of computational technologies (Fig. 9.6). In cases of facial anomalies, the use of 3D ultrasound has improved the accuracy of detection of facial clefts (Rotten and Levailant 2004). In CNS abnormalities, assessment of the corpus callosum is now possible using the C-plane of 3D volumes (VCI) (Fig. 9.7), and simultaneous visualisation with 3D ultrasound may improve the precise location of NTDs.

Transvaginal ultrasound and MRI

The greater resolution provided by high-frequency transvaginal transducers for structures within their 6–7-cm focal zone is ideal for visualisation of the first-trimester fetus.

MRI of the fetus was first described in the 1980s. Recently, faster capture times have helped to counter the problems created by fetal movements (Fig. 9.8). Although MRI has been used to aid the prenatal diagnosis of many conditions, its strength lies in assessing intracranial anatomy, and in particular the posterior fossa. Conditions including agenesis of the corpus callosum are reliably detected by MRI; the recognition of neuronal migration disorders depends on the severity of the disorder and the gestation at which the MRI is made. MRI has a place in prenatal diagnosis, although experience in this form of fetal imaging is still being collected.

Screening strategies for Down syndrome

In the past, standard screening policy was to offer women over the age of 35 years chorionic villus sampling (CVS) or amniocentesis for karyotyping. As only 25–30% of trisomy 21 fetuses are born to 'older' mothers, and as utilisation in this group rarely exceeds 50%, it is hardly surprising that the birth prevalence of Down syndrome fell by only 15% with this strategy (Walker and Howard 1986). Newer policies, which increase detection rates without increasing the numbers undergoing antenatal karyotyping, have been introduced into practice. The UK National Screening Committee (2008) currently recommends a screening test for Down syndrome with a

detection rate greater than 75% and a false-positive rate of less than 3%, which is age-standardised and based on a cut-off of 1:250 at term. The committee also recommends that the detection rate is increased to greater than 90% with a false-positive rate of less than 2% from April 2010.

Biochemical

The average maternal serum alpha-fetoprotein (AFP) value in Down syndrome pregnancies is 0.7–0.8 multiples of the median (Wald and Cuckle 1987). As this association is largely independent of maternal age, the two were then combined to give each woman a specific age- and AFP-adjusted risk (Cuckle et al. 1987). Subsequently, raised human chorionic gonadotrophin (hCG) (Bogart et al. 1989), particularly the free β -hCG subunit, and low unconjugated oestriol (Canick et al. 1988) levels were found to be associated with trisomy 21. Again, in the absence of any relation to maternal age or each other, their levels and maternal age were next combined using an algorithm to predict fetal risk (Wald et al. 1988). The reason for these biochemical changes is not yet understood, but is thought to relate to functional immaturity, producing a delay in the normal gestational rise or fall. Cut-offs of 1:250–1:300 have shown a sensitivity of up to 70%, with a false-positive rate of 5%. The term 'false-positive' in this context describes the percentage of the population that would be given a high-risk result if the test were taken up by the entire population. Subsequent refinements using free β -hCG (Nicolaidis et al. 2005) and a prior dating scan (Gardosi and Mongelli 1993), and confining the assay to 15–18 weeks' gestation, have increased the accuracy of the test. Additional biochemical measurement of unconjugated oestriol (triple test) and with inhibin (quadruple test) improves the detection rate (Driscoll and Gross 2009). The quadruple test has a sensitivity approaching 80% for trisomy 21 with a fixed false-positive rate of 5% (National Collaborating Centre for Women's and Children's Health 2008). Detection rates are greater in older mothers (i.e. over 35 years of age), but this is at the cost of higher false-positive rates (Haddow et al. 1994).

As biochemical screening takes place in the mid-trimester, it does not allow susceptible women the option of first-trimester CVS for karyotyping. The drive now is to bring screening for aneuploidy into the first and early second trimester, to allow earlier detection and easier termination procedures to be performed.

Ultrasound plus biochemistry in first and second trimesters

There have been major advances in ultrasound screening for aneuploidy. In the first trimester (10–14 weeks) the association between increased NT (Fig. 9.9) and aneuploidy has been confirmed in several studies (Szabo and Gellen 1990; Nicolaidis et al. 1994a; Landwehr et al. 1996). The association is with trisomies 21, 18 and 13 in particular. A sensitivity, when related to crown–rump length and maternal age, of almost 80%, with a false-positive rate of 5%, has been reported by one group in a low-risk population cohort of 96 127 (Snijders et al. 1998).

Recently, NT measurement has been combined with two first-trimester biochemical markers to improve the efficacy of early screening for trisomy 21. Levels of free β -hCG are increased in the serum of mothers carrying a fetus with Down syndrome, while levels of pregnancy-associated plasma protein A are decreased. When this test is combined with NT, the combined test yields a detection rate of 90% for a similar false-positive rate (Stenhouse et al. 2004; Nicolaidis et al. 2005). The integrated test, which combines first-trimester screening (combined test) with second-trimester

In this case there was complete agenesis of the corpus callosum, which was confirmed by magnetic resonance imaging.

screening (AFP, oestriol and inhibin), further increases the detection rate of Down syndrome to 95% (Malone et al. 2005).

Recent attention has focused on the relevance of the presence/absence of the fetal nasal bone (Clark et al. 2003). In a series from King's College Hospital, London, UK, the nasal bone was absent in 43 of 59 (73%) trisomy 21 fetuses and in 3 of 603 (0.5%) chromosomally normal fetuses. The likelihood ratio, therefore, for trisomy 21 was 146 (95% confidence interval (CI) 50–434) for absent nasal bone and 0.27 (0.18–0.40) for nasal bone being present. Subsequent work by the same group (Cicero et al. 2003) has shown in a retrospective series that the integration of nasal bone screening into the OSCAR test (One-Stop Clinic for Assessment of Risk) would lead to a detection rate of 97%; alternatively, for a false-positive rate of 0.5%, the detection rate is 90.5%. There is some evidence that the detection rate increases when used in addition to the combined

test (Orlandi et al. 2005), although this has not been consistently reproduced by other groups (Kozłowski et al. 2006; National Collaborating Centre for Women's and Children's Health 2008). Additional ultrasound markers to increase the sensitivity and reduce the false-positive rates are also being assessed, including the ductus venosus waveform and tricuspid regurgitation (Kagan et al. 2009; Maiz et al. 2009).

Subtle markers of aneuploidy

With advances in ultrasound resolution, many structures not previously visualised, such as the digits, feet and soft tissues of the neck, can now be demonstrated. Accordingly, the minor malformations and abnormal postures characteristic of aneuploid neonates may be seen in utero. Postaxial polydactyly is found more frequently in

Fig. 9.8 Fetal magnetic resonance imaging. Sagittal view of a normal mid-trimester fetus.

Fig. 9.9 Transabdominal ultrasound view of a nuchal translucency measurement in a fetus at 12 weeks' gestation.

trisomy 13 than in 18, but ventricular septal defects are common in both (Wladimiroff *et al.* 1989). The profile of the trisomy 18 fetus reveals micrognathia and a protuberant upper lip (Benacerraf *et al.* 1986a). The hands remain clenched in trisomy 18, with characteristic overlapping of the fingers, and the typical rocker bottom and equinovarus deformity are found in the feet. The sonographic features of trisomy 21 are more elusive. These may include increased nuchal thickness (first or second trimester), mild renal pelvic

dilatation, hyperechogenic bowel, brachycephaly and hypoplasia of the middle phalanx of the fifth finger (clinodactyly).

Invasive procedures and prenatal diagnosis

Samples of fetal tissues suitable for karyotyping, biochemical analysis and DNA studies are obtained by CVS and amniocentesis. In many cases the choice of procedure is left to the patient, based on her informed perception of the relative advantages and disadvantages of each. Fetal blood sampling (FBS), a technically more difficult procedure, is performed after 18–20 weeks' gestation, not just for antenatal diagnosis but also for therapy. Each invasive procedure is associated with a small chance of procedure-related loss. In general, therefore, invasive procedures are offered rather than recommended to parents, who, after appropriate counselling, should be given time to consider the various risks of the condition being tested against those of the procedure.

Amniocentesis

Amniocentesis is the commonest invasive procedure for prenatal diagnosis. Most are done at 14–16 weeks' gestation, when the amniotic cavity contains 150–200 ml of fluid, allowing 15–20 ml to be withdrawn without complication (working rule is x ml withdrawn = x weeks in gestation). A 22G needle is inserted transabdominally and guided to a pool under ultrasound control (Fig. 9.10). Simultaneous ultrasound monitoring reduces the number of dry and bloody taps (Romero *et al.* 1985; de Crespigny and Robinson 1986) and obviates the rare risk of severe fetal trauma. It has thus replaced the older technique of 'semiblind' insertion following ultrasound identification of a pool. Transplacental insertions have been linked

Fig. 9.10 (A) Amniocentesis: the 22G needle is introduced under ultrasound guidance (from top left). (B) Chorionic villus sampling: the 18G needle is introduced under ultrasound guidance (from top left).

with an increased miscarriage rate (Tabor et al. 1986; Kappel et al. 1987) and should be avoided. Even with an extensive anterior placenta, a small window avoiding the placenta can usually be found.

Patients are quoted a risk of spontaneous miscarriage attributable to the procedure of 1%, based on the results of the only randomised controlled trial (RCT; Tabor et al. 1986). Amniotic fluid contains cells desquamated from fetal skin, gastrointestinal, urogenital and respiratory tracts, and the amnion. In view of their small number, up to 2 weeks' cell culture is required prior to cytogenetic analysis, although with new techniques this period is shortening. A major disadvantage of amniocentesis is that termination of affected fetuses is not performed until well into the mid-trimester. Although amniotic fluid can be satisfactorily obtained and cultured at 11–13 weeks (Hanson et al. 1987; Benacerraf et al. 1988), the risks are increased with a greater miscarriage rate than with CVS (Nicolaidis et al. 1994b), and therefore is not recommended.

Approximately 0.5% of amniotic cell cultures fail to grow, and maternal cell contamination leads to diagnostic difficulty in 0.2% (Thirkelsen 1979; Reid et al. 1996).

Fluorescent in situ hybridisation (FISH; Ch. 8) was introduced to allow rapid detection of trisomy 13, 18 and 21 together with sex chromosome aneuploidies. FISH allows the detection of specific DNA sequences with chromosome-specific painting probes.

Quantitative fluorescent polymerase chain reaction (QF-PCR), a more recent technique, is a rapid method of detection of trisomy 13, 18 and 21 and sex chromosomes. Compared with FISH, this technique is entirely automated, quicker, feasible on fewer cells and more cost-effective with comparable detection rates (Hultén et al. 2003; Nicolini et al. 2004; Chitty et al. 2006). Maternal cell contamination is also much more readily identified (Hultén et al. 2003). At present in the UK, the National Screening Committee advocates the use of QF-PCR for the detection of trisomy 13, 18 and 21 in women with high-risk screening results but with normal ultrasound. Full karyotype is only advocated in cases with abnormal ultrasound findings (including NT ≥ 3 mm) or family/previous

history of chromosomal abnormalities. Most undetected karyotype abnormalities as a result of this clinical policy are not clinically significant (Caine et al. 2005).

Chorionic villus sampling

Although obtaining chorionic tissue suitable for cytogenetic and biochemical analysis was first reported more than 30 years ago (Mohr 1968), CVS was only introduced into clinical practice in the mid-1980s. CVS was originally performed transcervically, but is now most commonly performed transabdominally (Fig. 9.10). Safety appears to be better with the transabdominal route (miscarriage rates 1% versus 4%) (Jackson et al. 1992; Smidt-Jensen et al. 1992). Initially, CVS was performed between 8 and 12 weeks. However, concern was raised following a report of limb reduction defects, some in association with the oromandibular syndrome (Firth et al. 1991, 1994). In all cases, CVS was performed before 66 days' gestation, and by single-needle transabdominal aspiration. Subsequent population and case-control studies have been unable to confirm any link (Froster and Jackson 1996), but theoretically it seems plausible that a procedure which may cause embolism, thrombosis or vasoconstriction at the time of limb bud formation may lead to such malformations. Thus, it has been recommended that CVS be performed after 10 weeks' gestation (Kuliev et al. 1993; Rodeck 1993). CVS rates remain high owing to first-trimester combined screening leading to aneuploidy testing, and for cases requiring genetic molecular testing.

The CVS-related fetal loss rate before 28 weeks above the background rate is 1–2% in centres with much experience (Nicolaidis et al. 1994b). One problem with CVS is a 1.0–1.5% incidence of confined placental or pseudomosaicism, where a discrepancy exists between chorionic and fetal karyotypes, necessitating further investigation by amniocentesis (Hahnemann and Vejerslev 1997). In most cases, a bizarre aneuploid or polyploid mosaic is identified in the chorion, whereas the fetal karyotype, assessed from skin fibroblasts, is normal.

Fetal blood sampling

FBS is performed by direct ultrasound-guided needling of various fetal vessels. This is done as an outpatient procedure under local anaesthesia from 17 weeks' gestation. Sedation is rarely necessary. The most common approach, which involves inserting a 20G needle transabdominally into the umbilical vein about 1 cm from the placental cord insertion (Daffos *et al.* 1983), yields an adequate sample in 97% of cases (Daffos *et al.* 1985). Maternal contamination from inadvertent intervillous sampling is ruled out before removal of the needle by comparing the sample's MCV distribution, determined rapidly on a particle size analyser, with that of the mother (Rodeck 1980). Even at term, fetal MCV, which declines rapidly with gestation, remains significantly higher than that of healthy mothers (Fisk *et al.* 1989). The vein is the preferred vessel to sample, being simpler and safer (Weiner 1987); accidental sampling of the artery can be confirmed by ultrasonic observation of the direction of flow following injection of sterile saline (Nicolaidis *et al.* 1986d). When there is difficulty approaching the cord insertion because of obesity, oligo- or polyhydramnios, or fetal position, blood may be aspirated from the intrahepatic portion of the fetal umbilical vein (Koresawa *et al.* 1987; Nicolini *et al.* 1988c). Although FBS from the intrahepatic vein is more difficult than at the cord insertion, it obviates the need for laboratory confirmation of its source, and in multiple pregnancies the operator is certain as to which fetus is sampled (Bang 1983).

Determining the loss rate attributable to FBS is difficult, as fetal demise in the weeks after the procedure may instead be due to the underlying high-risk indication. This was clearly demonstrated in one series, which showed increased loss rates in procedures performed on sicker fetuses, i.e. prenatal diagnosis (2%), fetal structural abnormality (6%), assessment of severe FGR (14%), and hydrops (25%) (Maxwell *et al.* 1991). A reported summation of all the published series calculated an overall loss rate in procedures performed in low-risk cases of 2.7% (Ghidini *et al.* 1993), although others have reported a lower loss rate of 0.9% (Weiner and Okamura 1996), and this figure has been corroborated by the US International Registry (Megerian and Ludomirsky 1994). Such results are only achieved after considerable training and experience. Most losses are due to cord haematoma, cord tamponade or haemorrhage, and, unlike losses after CVS or amniocentesis, are apparent at the time of the procedure. In late pregnancy, emergency caesarean section is performed to salvage these infants, although some may be damaged. Intra-amniotic bleeding is observed ultrasonically after 40% of samplings (Daffos *et al.* 1985; Weiner 1987), and a histological study of cords within 48 hours of FBS showed that a degree of extravasation occurs in all cases (Jauniaux *et al.* 1989). This bleeding is almost always transient, owing to the abundance of thromboplastins in amniotic fluid (Ney *et al.* 1989).

Skin and muscle biopsy

Prenatal diagnosis of many severe genodermatoses necessitates histological and ultrastructural examination of fetal skin, obtained at 18–22 weeks, initially by fetoscopy (Rodeck *et al.* 1980) but more recently by ultrasound-guided techniques (Bang 1985). The usual site chosen is the fetal buttock or leg. In a review of 269 pregnancies at risk of severe inherited skin disease the main indication for fetal skin biopsy was the risk of recurrence of epidermolysis bullosa. In such families, in over 90% of cases a prenatal diagnosis was established (Fassihi *et al.* 2006). Epidermolysis bullosa letalis is characterised by separation of the epidermis from dermis at the lamina lucida on light microscopy, and a paucity of hemidesmosomes on electron microscopy (Rodeck *et al.* 1980) (Ch. 32). The

prenatal diagnostic features of epidermolysis bullosa dystrophica, epidermolytic hyperkeratosis, harlequin ichthyosis and Sjögren–Larsson syndrome have similarly been described (Elias *et al.* 1980; Golbus *et al.* 1980; Kusseff *et al.* 1982). In oculocutaneous albinism, in which there is a lack of active melanin synthesis in hair bulb melanocytes, the biopsy must be taken from a hair-bearing area such as the scalp (Eady *et al.* 1983). In the review above, over a 25-year period the miscarriage rate for fetal skin biopsy was approximately 1% (Fassihi *et al.* 2006). Fetal skin scarring was observed postnatally in only 6 of the 191 cases.

Although DNA analysis is available for the diagnosis of the most common muscular dystrophies, most notably Duchenne muscular dystrophy, there are circumstances when a direct fetal muscle biopsy is required. This is usually when genetic testing has proved inconclusive. The procedure is performed under ultrasound control with the biopsy forceps guided into the outer aspect of the fetal buttock so as to avoid major structures.

Fetal medicine

With the combination of ultrasound and invasive procedures, several conditions can be managed more rationally than in the past, such as congenital malformations, maternal exposure to infectious agents and FGR. In others, the fetus can be treated; intravascular transfusion (IVT) has greatly improved the survival of alloimmunised fetuses, making it thus far the best model for fetal therapy.

Management of non-lethal malformations

Table 9.1 lists the risks of chromosomal and other structural malformations associated with common non-lethal congenital malformations. These are considerably higher for anomalies detected in utero than at birth. For example, in the literature the risk of an abnormal karyotype for infants with congenital heart disease is 5–10% and for exomphalos 10%, compared with risks of 32% and 66%, respectively, from antenatal studies (Nicolaidis *et al.* 1986b; Copel *et al.* 1988a). Multiple malformations carry a 10-fold higher risk of aneuploidy than isolated malformations (Snijders *et al.* 1996). The demonstration of any fetal anomaly on ultrasound therefore prompts a detailed search for other abnormalities. Rapid karyotyping by FBS, amniotic fluid FISH or transabdominal CVS is offered. This is recommended not only in the mid-trimester to allow termination of aneuploid pregnancies, but also in the third trimester, where knowledge of a serious chromosomal defect may alter antenatal and intrapartum management, including mode of delivery. Furthermore, termination of pregnancy after 24 weeks' gestation is legal in the UK if there is a substantial risk that the fetus has an abnormality that would result in the birth of a child with a serious handicap. Karyotyping should also be performed for conditions where the risk of intrauterine death (IUD) is high, such as hydrops, because postmortem autolysis may jeopardise subsequent chromosomal studies and thus future genetic counselling. Indeed, postmortem karyotyping following termination for fetal abnormality has a 27% failure rate, and therefore pretermination sampling is advised (Kyle *et al.* 1996).

The option of termination of pregnancy is offered for severe malformations and support given to those who wish to continue through to delivery despite a poor prognosis. Other malformations are suitable for early postnatal correction, such as certain cardiac defects, duodenal atresia and gastroschisis. Intrauterine surgery may have a role in a few situations, but less so than was originally hoped. The significance of antenatal detection of some conditions, such as

Table 9.1 Reported frequencies of chromosomal and other structural abnormalities in fetuses with malformations detected in utero. The risk of aneuploidy will be lower if the malformation is isolated, and for the softer markers the risk will vary with maternal age

CONDITION	ANEUPLOIDY (%)	STRUCTURAL MALFORMATIONS (%)
Hydrocephalus	10–15	30–60
Cystic hygroma	45–80	15–65
Non-immune hydrops	3–15	25
Cleft lip/palate	1	15–50
Congenital heart disease	25–30	10–20
Diaphragmatic hernia	20–30	17–55
Tracheo-oesophageal fistula	15	50–60
Duodenal atresia	30–35	50–70
Exomphalos	50–65	60–75
Multicystic kidney	5–10	12–40
Pelviureteric junction obstruction	1–2	20–27
Posterior urethral valves	6–24	25–40

pelviureteric junction obstruction or multicystic kidney, is not so much the alteration of perinatal management as the initiation of timely investigation and follow-up in infancy.

The worse prognosis for abnormalities diagnosed in utero rather than neonatally largely reflects the increased risks of aneuploidy, multiple malformations and IUD. Whereas cystic hygroma at birth carries an excellent prognosis following surgical correction, the same-named lesion detected in utero leads to survival in less than 5% (Abramowicz et al. 1989; Langer et al. 1990). This high loss rate, which applies equally to euploid fetuses, reflects the frequency of hydrops and hypoxaemia in this condition (Tannirandorn et al. 1990).

Fetal growth restriction (Ch. 10)

The term 'small for gestational age' (SGA) describes both fetuses that are constitutionally small and those with FGR. Approximately 50–70% of fetuses with a birthweight <10th centile are constitutionally small. However, as a group, SGA fetuses are at higher risk of IUD, birth hypoxia, neonatal complications, impaired neurodevelopment and, according to the Barker hypothesis, potential hypertension and diabetes in later life.

While FGR may be suspected by abdominal palpation and measurement of the symphyseal–fundal height, the diagnosis is made ultrasonographically, with the abdominal circumference and/or estimated fetal weight <10th centile. Serial measurements are superior to single estimates not only in the prediction of genuine FGR but also in predicting poor outcome.

The incidence of a fetal karyotype abnormality in FGR is as high as 6–16% (Eydoux et al. 1989; Nicolaides and Economides 1990; Nicolini et al. 1990a), although this risk is based on series of referred patients in which severe FGR, often with oligohydramnios and malformations, was the indication for rapid karyotyping. With severe FGR and no structural malformations, the risk is lower, 2–3% (Snijders et al. 1996). The risk of aneuploidy remains remote in the milder forms of FGR, which complicates 5–10% of all pregnancies in the late third trimester. Karyotyping warrants consideration in severe FGR, when associated with fetal malformations, or in the

presence of normal liquor volume or uterine or umbilical Doppler studies.

While ultrasound has assisted in establishing the diagnosis of FGR, the role of Doppler ultrasound has been extensively researched in terms of: (1) prediction of risk and (2) monitoring affected pregnancies with FGR. The role of uterine artery Doppler analysis in predicting FGR appears to be limited, even in high-risk pregnancies (Chien et al. 2000), while screening a low-risk population with umbilical artery Doppler does not reduce perinatal mortality or morbidity (Bricker and Nielson 2004). However, monitoring of high-risk pregnancies with umbilical artery Doppler has been shown to reduce perinatal morbidity and mortality (Alfirevic and Neilson 1995; Neilson and Alfirevic 2003). In particular, absent end-diastolic flow (EDF) is associated with adverse perinatal outcome (Rochelson et al. 1987). Although acidaemia and hypoxaemia are unlikely in the presence of EDF, 45–80% of fetuses with absent EDF are acidaemic (pH <7.31) and 79–100% hypoxaemic (Nicolaides et al. 1988a; Nicolini et al. 1990a).

With knowledge of the fetal compensatory response to hypoxia by redistribution of blood flow, pulsed Doppler investigation of the involved fetal vessels provides more information about fetal condition. Redistribution of blood flow away from the kidneys (leading to oligohydramnios), gut (leading to hyperechogenic bowel) and skin towards the brain, adrenals and heart can be demonstrated by increased flow velocity within the MCA, and decreased flow velocity within the descending aorta. Alterations in the venous circulatory system may represent an end-stage response with cardiac decompensation, which can be measured at the level of the ductus venosus (Hecher et al. 1995a). Increased pulsatility and reversed velocity at the time of atrial contraction may be found. Decision-making regarding timing of delivery is currently based on combining the results of Doppler studies with growth velocity, amniotic fluid levels and CTG. The risk of prematurity associated with delivery is balanced against the continued exposure to in utero fetal hypoxaemia and acidaemia. In a recent multicentre study of neonates with prenatally diagnosed intrauterine growth restriction born before 33 weeks, although low Apgar score and Doppler changes were independent predictors of perinatal survival, gestational age greater than

29 weeks and 2 days and birthweight threshold of 600 grams were better predictors of survival (Baschat et al. 2007). In addition to immediate increased risk of perinatal morbidity and mortality, the risk of long-term neurodevelopmental delay in surviving infants is also increased (Rijken et al. 2007; Delobel-Ayoub et al. 2009; Petrini 2009). The longer term effect of fetal compensation in response to hypoxia is difficult to disentangle from the effects of prematurity. The Truffle study is a European RCT of delivery based on either early or late changes in venous circulation compared with delivery based on CTG changes suggestive of fetal hypoxia. The primary outcome of this trial is survival without neurodevelopmental delay at 2 years of age corrected for prematurity.

Red cell alloimmunisation

Despite a dramatic decline in incidence, maternal sensitisation has not disappeared, for a variety of reasons, including antenatal sensitisation, prophylaxis failure and antibodies other than anti-D. Untreated, 45–50% of affected infants will have no or only mild anaemia, and 25–30% will have moderate anaemia posing neonatal problems only. The remaining 20–25% develop hydrops and usually die in utero or neonatally; in half, the hydrops develops prior to 30 weeks (Bowman and Pollack 1965). The aim of antenatal management is to identify severely affected fetuses, to correct their anaemia by transfusion, and then deliver them at the optimal time. At each gestational age the risks of invasive monitoring are weighed against those of conservative management and delivery. A suggested algorithm for the management of these cases is outlined in Figure 9.11.

Anti-D prophylaxis

RhD-negative women are at risk of sensitisation from fetomaternal bleeding, not only at delivery but also in other situations, such as external cephalic version and amniocentesis. Although the prevention programme has reduced neonatal deaths attributable to haemolytic disease of the newborn (HDN) from 18.4/100 000 in 1977 to 1.3/100 000 in 1992, there remains a sensitisation rate of around 1.5% among Rh-negative women. Administration of 500 IU of anti-D at 28 and 34 weeks can reduce the risk of immunisation to 0.2% (Crowther 2003). Anti-D prophylaxis is now recommended by the Royal College of Obstetricians and Gynaecologists (2003) and the National Institute for Health and Clinical Excellence (2003), with either a dose of 500 IU at 28 and 34 weeks, or a single larger dose of 1500 IU early in the third trimester. The rationale is that all Rh-negative women are at risk from hidden bleeds. The introduction of routine antenatal prophylaxis at 28 weeks in the UK has reduced the incidence of new sensitisation (Chilcott et al. 2003; Crowther 2003).

It is, however, important to note that clinically significant disease can be caused by other red cell alloantibodies such as Rh-c, Kell, Rh-E and Fy^a (Duffy). At present, immunoprophylaxis is not available for non-RhD disease and so immunisation will continue to occur.

Antenatal screening and management of RBC alloimmunisation

Routine serological testing of women is carried out:

- to identify pregnancies at risk of fetal and neonatal alloimmune disease (HDN)
- to identify RhD-negative women who require antenatal anti-D prophylaxis
- to provide compatible blood swiftly in emergencies.

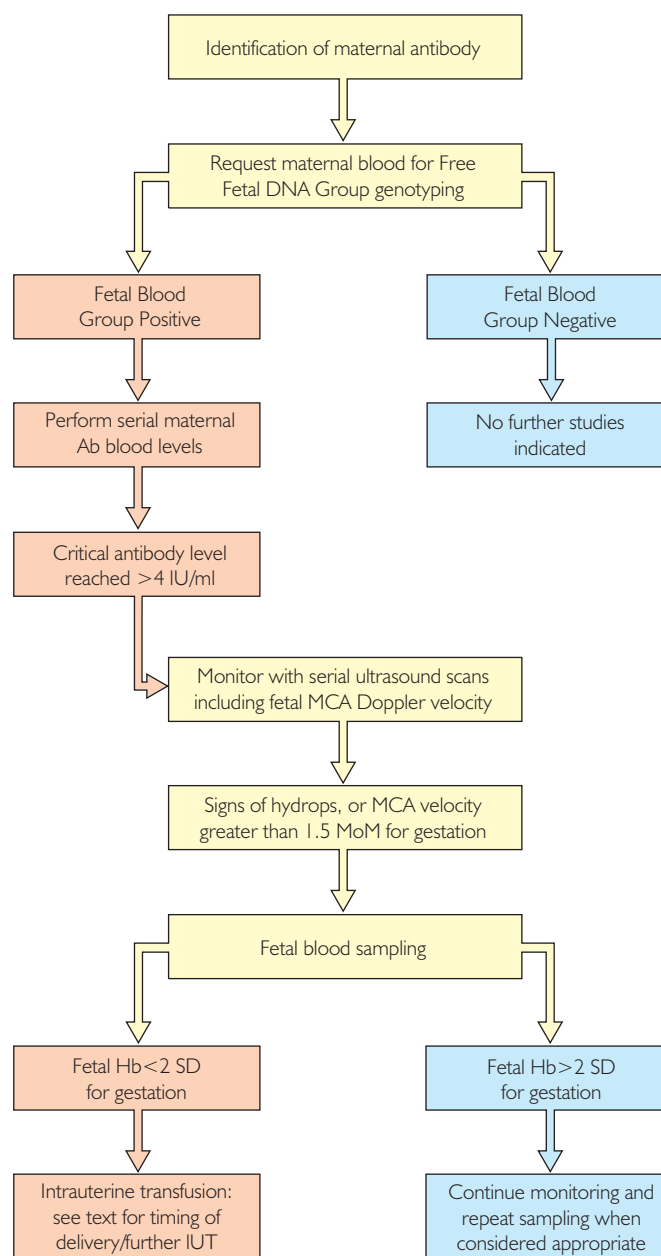

Fig. 9.11 A proposed algorithm for the management of red cell alloimmunisation.

All women who have no antibodies at 10–16 weeks' gestation should be tested once again between 28 and 36 weeks. Some workers believe that RhD-negative women should have two further tests, one at 28 weeks and one at 34–36 weeks, but sensitisation late in pregnancy is unlikely to result in HDN requiring treatment.

Quantification of the anti-D has simplified interpretation of positive antibody screens. Severe fetal anaemia is not expected at <4 IU/ml (Bowell et al. 1982) and is rare (0.25%) at <10 IU/ml. Further evaluation therefore is warranted at levels >4 IU/ml. Above this threshold, antibody levels have a limited role as they correlate poorly with the degree of fetal anaemia (Nicolaides et al. 1985b), although a rising level suggests an increase in severity. Prior to non-invasive methods of assessment, a level >15 IU/ml indicated the need for invasive assessment of fetal anaemia. No such similar

cut-off levels apply to anti-c, Kell and Fy^a, and close monitoring is required in these cases, even with low titres.

When the fetus has been shown to be Rh-positive, the maternal antibody concentration should be checked every 2–4 weeks. Monitoring is now primarily with assessment of blood velocity in the MCA (see below). Additional ultrasonographic assessments include measurement of placental thickness, umbilical vein diameter, spleen and liver size (Chitkara *et al.* 1988; Nicolaides *et al.* 1988c; Roberts *et al.* 1989) or Doppler assessment of velocities in the descending aorta and ductus venosus (Copel *et al.* 1988b; Nicolaides *et al.* 1990; Oepkes *et al.* 1993, 1994), although none have been shown to be as reliable as MCA Doppler measurements in predicting the degree of anaemia. While the demonstration of fetal ascites indicates severe anaemia (PCV <15%, Hb <4 g/dl) in the mid-trimester, ascites only actually develops in two-thirds of fetuses with an Hb <4 g/dl (Nicolaides *et al.* 1985b). Anaemia of this degree is not associated with hypoxaemia, but is associated with increased fetal lactate levels, suggesting tissue hypoxia (Soothill *et al.* 1987). This is unlikely to cause developmental delay, but should be corrected as soon as possible by transfusion.

Determination of paternal zygosity and fetal genotype

Following the identification of antibodies in the maternal circulation, determination of the paternal Rh status is important. Approximately 15% of the UK population are RhD-negative, and, of the positive fathers, 56% are heterozygous for the D-gene, with a 50% chance of passing this on to the fetus. In cases of proven paternal heterozygosity, fetal antigen status should then be determined. Recent advances, since the identification of the Rh gene in 1991 (Colin *et al.* 1991), have allowed fetal antigen status to be determined, firstly from amniotic fluid (Bennett *et al.* 1993) and now from maternal blood by identification and analysis of free fetal DNA (Lo *et al.* 1998). This latter technique is known as non-invasive prenatal diagnosis (NIPD) and has replaced invasive testing in routine clinical service in the UK (Finning *et al.* 2002; Wright and Chitty 2009). At present NIPD is only offered to women with RhD antibodies who are at risk of pregnancies complicated by HDN. It has the potential use for routine screening in all RhD-negative women, and studies are currently underway to evaluate its performance as a screening test (Maddocks *et al.* 2009; Wright and Chitty 2009). Concerns of persistence of free fetal DNA from one pregnancy to the next have been largely discounted by the demonstration of its rapid clearance from the maternal circulation soon after birth.

Non-invasive assessment for fetal anaemia

Recent advances in Doppler imaging have resulted in a shift in practice away from early invasive assessment (and hence an avoidance of increased maternal sensitisation). Attention has focused on the Doppler velocimetric assessment of the MCA to predict fetal anaemia (Fig. 9.12). The rationale is that the MCA responds quickly to hypoxaemia owing to the strong dependence of the brain on oxygen and also reflects the hyperdynamic circulation associated with anaemia. Several groups have shown a strong negative correlation between either peak systolic velocity or mean velocity and fetal Hb or haematocrit (Mari *et al.* 2000; Teixeira *et al.* 2000; Abdel-Fattah *et al.* 2002). In the largest series, the peak systolic velocity in the MCA predicted moderate or severe anaemia without hydrops in 100% of cases, with a false-positive rate of 12% (Mari *et al.* 2000). The demonstration of increased velocity in the MCA indicates a strong likelihood of fetal anaemia. At this point, invasive testing is

Fig. 9.12 Colour Doppler appearances of the circle of Willis and the middle cerebral arteries.

indicated. Use of MCA monitoring compared with more traditional methods of monitoring appears to allow the first invasive procedure to be performed later in gestation without compromising fetal well-being (Bartha *et al.* 2006).

Fetal blood transfusion

FBS allows direct assessment of fetal PCV and Hb, and permits transfusion to be performed at the same procedure if anaemia is detected. However, as FBS has a loss rate, and provokes fetomaternal haemorrhage and thus increases antibody levels in 70% of procedures in which the placenta is transgressed (Nicolini *et al.* 1988a), it is avoided until MCA Doppler measurements predict significant anaemia.

IVTs are now given by ultrasound-guided FBS (Bang *et al.* 1982; Berkowitz *et al.* 1986; Nicolaides *et al.* 1986c). The decision to administer an IVT is based on the PCV or Hb at FBS. Most use an Hb of less than 2 SD for the gestation (Nicolaides *et al.* 1988a, b) as an indication for transfusion; some use an absolute haematocrit below 30%. The needle tip is kept within the umbilical vein and fresh Rh-negative packed cells compatible with the mother are infused at 10–15 ml/min. The fetal heart rate and flow of infused blood are monitored on ultrasound to guard against inadvertent needle dislodgement and cord tamponade. The volume transfused is determined by consideration of the estimated fetoplacental volume and the fetal and donor PCV (Nicolaides *et al.* 1986c) or Hb (Nicolaides *et al.* 1988b), according to published nomograms. The PCV is rechecked after transfusion, and, if less than the desired 40–45%, a further increment is given.

The timing of the second transfusion should be based on the pre- and posttransfusion fetal Hb from the first transfusion, and from serial MCA Doppler velocities. After the second transfusion, the rate of fall in PCV in the fetus may be determined (when the PCV is estimated to have fallen to 20–25%) and the timing of subsequent transfusions arranged, although these again are often modified by the MCA Doppler velocities. Kleihauer testing of fetal samples indicates that erythropoiesis is usually completely suppressed after two or three transfusions (Nicolini *et al.* 1989c). As the donor blood in the fetal circulation is not susceptible to immune destruction, the rate of fall in PCV declines with increasing transfusions and thus the interval between procedures can be increased. The same principles are used in scheduling delivery between 36 and 38 weeks. Once an intrauterine transfusion has been performed, the timing of delivery will depend on when the last transfusion was performed and how many days it is likely to take for the Hb to fall

to a level about 2 SD below the mean. Intrauterine transfusions are not usually performed after 36 weeks. In a woman with no previous history but an antibody level above 4 IU/ml (or 1:16 titre), the delivery can be planned at 37–38 weeks of gestation.

Survival

With serial IVTs, survival rates of 78–95% have been achieved in severely affected fetuses (Nicolaidis 1986c; Poissonier et al. 1989). One series has reported that, in almost 600 IVTs, intact survival was 98% in those commenced in non-hydrotic fetuses at greater than 24 weeks, and 70% in hydrotic fetuses less than 24 weeks' gestation (Harman 1995). There are few follow-up studies focusing on morbidity, but one published study suggested that, when prematurity is removed, long-term morbidity secondary to intrauterine transfusion is low (Hudon et al. 1998). Therefore, the prognosis is now extremely optimistic. Fetal mortality correlates inversely with gestational age, and operator experience is undoubtedly also of importance.

Fetal thrombocytopenia

Alloimmune thrombocytopenia (Ch. 30)

Perinatal alloimmune thrombocytopenia complicates at least 1:3500 births, with intracranial haemorrhage (ICH) affecting 10–20% (Kamphius et al. 2010). Maternal antiplatelet antibodies cross the placenta, in a situation analogous to Rh disease. The consequent fetal thrombocytopenia may be profound, with a risk of spontaneous ICH in utero, particularly in the third trimester (Morales and Stroup 1985; de Vries et al. 1988; Friedman and Aster 1989), but it may occur as early as 18 weeks' gestation. The human platelet-specific antigens are biallelic polymorphisms which involve the platelet surface glycoproteins. Recently, a nomenclature of human platelet antigens (HPAs) has been developed (von dem Borne and Decary 1990). At present, HPAs 1–5 have been recognised. The genetic basis for these five HPAs has been identified, all involving a single point mutation in the DNA coding for the glycoproteins involved (Williamson et al. 1992). The most common is HPA 1, which has a high-frequency (85%) or a low-frequency (15%) antigen. Only 2% of women will be homozygous for the low-frequency 'b' allele, and thus at risk of developing antibodies and alloimmunisation. Fortunately, the actual occurrence of alloimmunisation is much rarer than this (0.06%) (Blanchette et al. 1990) because the development of antibodies is dependent on the human leukocyte antigen (HLA) type. HLA-Drw52a and HLA-Dr3 are most commonly associated with the development of HPA 1a antibodies. The incidence of women who were HPA 1a-negative was 2% in a screening and intervention programme of 100 000 unselected pregnant women in Norway. Anti-HPA 1A antibodies were detected in approximately 10% of women who were HPA 1a-negative. In the 161 HPA 1a-positive infants of negative mothers, there were 55 cases of severe thrombocytopenia and two cases of ICH (Kjeldsen-Kragh et al. 2007).

Management

The most reliable method of assessing likely disease severity is by inference from previous pregnancies: usually, a current pregnancy will be as severely affected as, or more affected than, previous pregnancies (Nicolini et al. 1991). This guides when investigation and treatment should begin, which may be as early as 18 weeks' gestation. Percutaneous FBS and estimation of fetal platelet count is the only way to determine whether a fetus is affected (Daffos et al. 1988b).

There are several management options available, and therefore patient care should be tailored dependent on previous history and parental preference.

Fetal platelet transfusions

These are used to cover the samplings and delivery, but may also be employed in a prophylactic manner, with weekly transfusions during the second and third trimesters and delivery once lung maturity is achieved. This prophylactic regimen was favoured in Europe until recently, but is arduous for the mother. In practice, transfusions are usually commenced at 26–28 weeks' gestation to cover the time of greatest risk (Nicolini et al. 1988b), although in cases of severe disease the first transfusion may be indicated as early as 20–22 weeks. A normal platelet count does not exclude the diagnosis, and therefore the procedure should be repeated at 28–32 weeks, unless from sampling amniotic fluid or fetal blood the fetal platelet type is found to be compatible.

Intravenous immunoglobulin

Cumulative data suggest that intravenous immunoglobulin (IVIG) is an important treatment option in this condition. Maternal infusion is less invasive and simpler than direct fetal sampling. However, it is expensive. Reports of maternal IVIG raising the fetal platelet count are variable (Bussel et al. 1988; Nicolini et al. 1990b). It may be that the IVIG has a preventive effect on ICH, other than by increasing the fetal platelet count. In a series of 54 women with thrombocytopenic fetuses due to alloimmune thrombocytopenia given IVIG weekly, in whom 10 had a previous infant with ICH, no ICH occurred and yet 20% showed no increase in the platelet count with therapy (Bussel et al. 1996). Data from observational studies suggest comparable neonatal outcomes between cases managed only using IVIG compared with those managed using IVIG and fetal sampling (Radder et al. 2001; van den Akker et al. 2007). Most centres currently advocate the use of repeated IVIG from early in the second trimester with possible fetal sampling and transfusion later in the second trimester based on previous history, followed by delivery by caesarean section 2–4 weeks before term (Kanhai et al. 2007). Other groups now rely on this treatment solely (Radder et al. 2001), or a combination of IVIG and platelet sampling, with the latter's timing and frequency dependent on the previous history and platelet count.

Conservative

The final option is to follow the fetus regularly by ultrasound and, in countries where late termination is permitted, to offer termination if ICH is found. This approach may be suitable in cases in which there is no severe history and hence the risk of ICH versus a complication from recurrent sampling or transfusion is low. Sampling may be performed prior to delivery to assess whether a transfusion is required to cover this (Kaplan et al. 1988).

There is no clear evidence to demonstrate that one treatment strategy is superior to the others. Although prophylactic platelet transfusions may be the most effective, there is a considerable procedure-related loss secondary to the serial procedures (Weiner et al. 1994), and therefore this needs to be weighed against the overall risk of ICH with untreated disease. Currently, the balance appears to be swinging to weekly maternal IVIG, and only limited FBS, with platelet transfusion if necessary.

Autoimmune thrombocytopenic purpura

Transplacental passage of antibodies in maternal immune thrombocytopenic purpura (ITP) also produces fetal thrombocytopenia. The older literature suggested that the 50% of infants with

thrombocytopenia had a risk of ICH during vaginal delivery (Hegde 1985), and accordingly FBS for fetal platelet count determination prior to labour used to be performed in pregnancies complicated by ITP to decide on the mode of delivery (Moise et al. 1988; Scioscia et al. 1988). More recent studies show a low incidence of severe fetal thrombocytopenia (5–20%) or infant morbidity with maternal ITP (Kelton et al. 1982; Weiner 1990; Burrows and Kelton 1993), with no documented cases of antenatal ICH or ICH attributable to mode of delivery, even in cases of severe thrombocytopenia. There is no correlation between maternal and fetal platelet counts (Payne et al. 1997); the level of platelet-associated antibody does not correlate with fetal thrombocytopenia (Burrows and Kelton 1990; Samuels et al. 1990).

Management

Treatment for maternal thrombocytopenia includes steroids, splenectomy (outside pregnancy) and IVIG to raise the platelet count prior to delivery. There is no evidence that these treatments affect fetal platelet count. Fetal morbidity appears extremely low in this condition, so that opinion has moved away from fetal intervention unless there has been a strong history of a previously affected child with severe thrombocytopenia.

Congenital infections (Ch. 39.2)

Counselling a woman after perinatal exposure to teratogenic infectious agents previously involved quoting empirical risks. Now, direct serological investigation of the fetus and DNA analysis of fetoplacental tissues can be used to determine whether fetal infection has occurred. In rubella this may facilitate continuation of pregnancy, whereas in toxoplasmosis it determines the choice of antimicrobial therapy. FBS has no role in evaluating fetal status in maternal human immunodeficiency virus infection, as the procedure itself could infect the fetus.

Rubella

Prenatal diagnosis of rubella infection is usually indicated following maternal exposure in the early second trimester, or where doubt exists as to whether exposure in the first trimester resulted from primary infection or reinfection. Rubella-specific IgM is detected in fetal serum by radioimmunoassay (Morgan-Capner et al. 1985; Daffos et al. 1988a), provided that FBS can be delayed until 21–22 weeks, when the fetal humoral response to infection becomes detectable. Even at 23 weeks occasional false-negative IgM levels have been reported (Enders and Jonatha 1987). To improve the accuracy of prenatal testing at this late gestation, fetal blood or other tissues are also tested by hybridisation with a cDNA probe to rubella virus (Craddock-Watson et al. 1989). Earlier in pregnancy the same technique can be used on CVS specimens (Terry et al. 1986), although concern remains that placental infection may not indicate fetal infection (Alford et al. 1964).

Congenital infection leads to the classic rubella triad of cataracts, congenital heart defects (most commonly pulmonary stenosis) and deafness (Gregg 1941). With advancing gestation, transplacental passage reduces, with congenital infection rates of 50% in the first month falling to just 10% by 3 months (Enders et al. 1988). In addition, the severity of the syndrome reduces with advancing gestation.

Cytomegalovirus

The most severe congenital infections are due to primary maternal cytomegalovirus infection. Primary infection is associated with a 40% transmission rate, although only 10% of those fetuses will

develop long-term sequelae, mostly hearing and learning defects (Peckham et al. 1987). Among the 5–10% who are symptomatic at birth, there will be a neonatal mortality of 30%, with long-term handicap in all survivors. Infection in earlier gestation results in higher transmission and poorer outcome.

Prenatal diagnosis is based on ultrasound findings and the detection of viral particles in the amniotic fluid (Davis et al. 1971), or, less commonly, in fetal blood. Specific IgM in fetal serum may also be diagnostic (Lange et al. 1982). Ultrasound findings include FGR, ascites or hydrops, intracranial calcification, ventriculomegaly and bowel echogenicity. Nevertheless, 90% of infants with congenital cytomegalovirus infection remain neurologically and developmentally normal. The risk of adverse outcome is increased if there is microcephaly, intracranial calcification, ventriculomegaly or evidence of a cerebral migration disorder (Ch. 40.8), and in these situations termination of pregnancy should be discussed.

Toxoplasmosis

Although, as pregnancy advances, maternal exposure leads to an increased risk of fetal infection, severity is greatest with exposure in the first trimester, with little chance of severe congenital disease after 20 weeks' gestation. Termination of an infected fetus remains an option, although fetoplacental infection is largely treatable (Desmots and Couvreur 1974). The aim of fetal testing is to allow optimal transplacental therapy, initially with maternal spiramycin (3 g/day) to prevent transplacental transmission, with the addition of pyrimethamine and sulfadiazine if fetal testing proves positive (Daffos et al. 1988a). These two drugs are directly antiparasitic and have been shown to limit fetal damage. They are not used in the first instance when information about maternal infection is known, but rather only when fetal infection is proven, because of the potential hazards to mother and fetus. The diagnosis of fetal infection is now made with PCR analysis of amniotic fluid, which has replaced the more cumbersome multiple testing that was previously required (Hohlfield et al. 1994). If fetal infection is proven, the prognosis is still likely to be good, although vision may be affected later. However, intracranial signs of calcification and/or ventriculomegaly are poor prognostic signs (Berrebi et al. 1994), and termination would be offered.

Parvovirus

Human parvovirus (B19) infection is associated with increased risks of miscarriage, hydrops and IUD (Anand et al. 1987), with an overall fetal loss rate of 9% in infected pregnancies (Public Health Laboratory Service 1990). Parvovirus is best identified in fetal blood or other tissues by dot-blot hybridisation, electron microscopy or, most commonly, PCR of B19-specific DNA (Sheikh et al. 1992). The mainstay of diagnosis, however, remains maternal serology in women with appropriate clinical symptoms. Anti-B19 IgM appears in the serum at the onset of illness and remains detectable for up to 3 months. IgG response begins after 7 days and persists, probably to confer lifelong immunity. FBS is not routinely indicated in pregnancies with maternal infection because at least 90% will result in livebirths and parvovirus does not seem to be teratogenic.

It is the profound fetal anaemia secondary to an infective erythroid aplasia that accounts for the significant mortality rate. Following documented maternal infection, close fetal monitoring for signs of anaemia is indicated. Assessment of the MCA velocity for early detection of anaemia may be useful (as with monitoring of fetuses at risk of alloimmunisation) for 12 weeks postexposure, as fetal anaemia may occur 1–11 weeks after maternal infection (Rodis et al. 1988). FBS and IVT are indicated in the presence of suspected

anaemia or hydrops. The incidence of coexisting fetal thrombocytopenia requiring platelet transfusion has been reported as high as 25% (Forestier et al. 1999; Simms et al. 2009). Hydrops without fetal anaemia has been documented and viral particles have been identified in the fetal myocardium, suggesting that a myocarditis may be contributory. It appears that profoundly anaemic fetuses which are salvaged by transfusion have a good prognosis, although more than one IVT may be necessary on occasion (Schwartz et al. 1988; Peters and Nicolaides 1990).

Tachyarrhythmias

Supraventricular tachycardia (SVT) is the most common fetal tachyarrhythmia, with rates between 200 and 300 beats/min. Atrial flutter and fibrillation often run at faster rates. As SVT is often intermittent, treatment is indicated only when SVT is sustained or associated with hydrops (Kleinman et al. 1985). In utero therapy seems preferable to delivery and neonatal treatment, as the fetus tolerates haemodynamic compromise better in utero, where gas exchange is not hindered by pulmonary oedema. Transplacental treatment by giving the mother digoxin leads to cardioversion in only 25–50% of non-hydrotic cases (Stewart and Wladimiroff 1987; Maxwell et al. 1988) and is usually not effective in the presence of hydrops (Frohn-Mulder et al. 1995). These poor results partly reflect difficulties in achieving therapeutic maternal levels owing to the increased intravascular volume and glomerular filtration rate of pregnancy.

The addition of second-line drugs, such as flecainide and verapamil, results in improved eventual cardioversion, with over 90% conversion (including fetuses with hydrops) with flecainide in one series (Ebenroth et al. 2001). The same group also demonstrated that the fetuses that required second-line therapy in utero had a significantly more complex postnatal course.

Reports of sudden death in adults with antiarrhythmics such as amiodarone have slowed their incorporation into fetal treatment. Direct fetal intravascular or intraperitoneal therapy may be useful in refractory cases or those with hydrops (Flack et al. 1993). Adenosine has been reported to cause a chemical cardioversion when injected directly into the fetal circulation, and then sinus rhythm was maintained by transplacental digoxin therapy (Kohl et al. 1995). This needs to be explored further in cases resistant to initial maternal treatment. Doses required are much higher per kilogram estimated fetal bodyweight than in the neonate, presumably to allow for transplacental passage into the maternal circulation, and to account for the enhanced fetoplacental blood volume.

Congenital heart block

Complete heart block in the fetus is rare, with a reported incidence of between 1:5000 and 1:20000. The intrinsic ventricular rate is around 50–65 beats/min and the heart usually enlarges and hypertrophies to compensate for the slow rate. Hydrops may occur as congestive heart failure develops.

Congenital heart block (CHB) with a structurally abnormal heart carries a poor prognosis (85% mortality), whereas with a structurally normal heart the prognosis is good (Machado et al. 1988). In 1966, the association between isolated CHB and maternal connective tissue disease was first described (Hull et al. 1966). Anti-Ro and anti-La (SSA and SSB) antibodies are present in 60–80% of cases, often in mothers with subclinical disease. These antibodies are most frequently found in women with Sjögren syndrome, or, less often, with systemic lupus erythematosus. Various therapeutic options based on maternal transplacental therapy are available, although none have shown proven efficacy. These include sympathomimetic agents to increase fetal heart rate and function (Johnson et al. 1994)

and maternal dexamethasone to suppress fetal myocardial inflammation (Bierman et al. 1989; Chua et al. 1991). In practice, these are only used with a fetal heart rate <50 beats/min, or signs of complication, including hydrops. Recurrence rate following one fetus with CHB due to immune antibodies is approximately 18% (Izmirly et al. 2010).

Abnormalities of amniotic fluid volume

Oligohydramnios

Causes of oligohydramnios in the mid-trimester include urinary tract malformations, preterm premature rupture of membranes (PPROM) and FGR, and at these gestations survival is less than 25% whatever the cause (Barss et al. 1984; Mercer and Brown 1986). Conditions with a lethal prognosis, such as renal agenesis and aneuploidies, should be ruled out. Absence of the acoustic window makes inspection of fetal anatomy difficult. Transvaginal ultrasound facilitates visualisation of the renal fossae, as does colour Doppler of the renal arteries (Sepulveda et al. 1995). If still equivocal, invasive procedures may be required, including amnioinfusion and/or instillation of fluid into the fetal peritoneal cavity (Nicolini et al. 1989d). Amnioinfusion of a warmed physiological solution not only restores the acoustic window, but also allows confirmation of PPRM, especially when a dye is added (Fisk et al. 1991).

As 5–10% of fetuses in pregnancies with severe oligohydramnios will be chromosomally abnormal (Hackett et al. 1987), rapid karyotyping is carried out at the time of amnioinfusion. In the rare case of a euploid fetus with oligohydramnios, intact membranes and an intact renal tract, there may be a role for serial amnioinfusions in the prevention of lethal pulmonary hypoplasia (Arulkumaran et al. 1990), which otherwise complicates at least 60% of cases of severe mid-trimester oligohydramnios (Moore et al. 1989).

Polyhydramnios

The more severe the polyhydramnios, the more likely that an underlying cause will be found. Using the maximum vertical pocket, mild and severe polyhydramnios have been arbitrarily defined as a deepest pool greater than 8 cm and 15 cm, respectively (Chamberlain et al. 1984). The amniotic fluid index (AFI) definitions for mild and severe polyhydramnios are values outside the 97.5th centile for gestation and an AFI >40 cm, respectively (More and Cayle 1990).

Exclusion of maternal diabetes is essential; thereafter, a detailed fetal assessment is mandatory. In one series, 11% of neonates had a structural anomaly (most notably tracheo-oesophageal fistula, oesophageal atresia, duodenal atresia or conditions that impair fetal swallowing such as arthrogryposis), which increased with increasing severity of the polyhydramnios (Dashe et al. 2002). If sonographic evaluation was normal, the risk of a major anomaly was just 1% with mild polyhydramnios, but 11% if severe. Aneuploidy was present in 10% of fetuses with sonographic anomalies and in 1% without. Overall the fetal loss rate was 4%, of which 60% had anomalies.

The increased risks of preterm labour and PPRM in polyhydramnios seem mainly confined to those with severe polyhydramnios, i.e. an AFI >40 cm or a deepest pool >15 cm (Carlson et al. 1990; Fisk et al. 1990b). Amniotic reduction (AR) has been used with anecdotal success in severe polyhydramnios in order to prolong gestation and relieve maternal discomfort (Queenan 1970; Feingold et al. 1986). Removal of relatively small volumes of amniotic fluid can restore amniotic pressure to normal (Fisk et al. 1990b), but usually larger volumes are removed to limit the number of procedures that may be required. Nevertheless, removal of

volumes greater than 6 litres at one time does carry the risk of precipitating abruption and/or preterm labour (Elliot et al. 1994).

Prostaglandin synthetase inhibitors have been used to reduce amniotic fluid in the past but are no longer recommended owing to potential fetal side-effects.

Multiple pregnancy (Ch. 23)

The incidence of twin pregnancies in the UK is 14.4 per 1000 births (National Health Service OPCS 1997), an increase of 25% compared with the early 1980s. The incidence is highest in older women (19.1 per 1000 in women aged 35–39 years in 1992), among whom a significant increase occurred owing to assisted reproductive techniques. This relatively small increase in frequency of multiple pregnancy will have a disproportionate effect on perinatal mortality and morbidity. Twin pregnancies have an eightfold increased risk of cerebral palsy, and triplet pregnancies a 47-fold increase (Patterson et al. 1993).

Up to a third of twin pregnancies are monozygotic, of which the majority share a single monochorionic placenta. For more information about zygosity, see Chapter 23. Perinatal morbidity and mortality in monochorionic twins is three- to fivefold higher than in dichorionic twins (Benirschke and Kim 1973; Neilson et al. 1989; Bejar et al. 1990); furthermore, previable losses are also significantly increased (Sebire et al. 1997). Much of the increase in risk is due to the presence of vascular anastomoses which are implicated in TTTS, and the co-twin sequelae after IUD of one twin.

Twin–twin transfusion syndrome

TTTS complicates approximately 15% of monochorionic diamniotic twin pregnancies (Sebire et al. 2000), and accounts for 15–17% of overall perinatal mortality in twins (Weir et al. 1979; Steinberg et al. 1990). It has classically been attributed to transfusion of blood via placental vascular anastomoses between the two fetal circulations. Vascular anastomoses are present in 96% of monochorionic placentas, and interfetal transfusion is a normal event in the majority of these pregnancies (Denbow et al. 2000). However, placentas from pregnancies affected by TTTS are characterised by two findings: first, an imbalance in interfetal transfusion is set up by the presence of unidirectional arteriovenous anastomoses, and, second, there is an absence of compensatory bidirectional arterioarterial anastomoses (Machin et al. 1996; Denbow et al. 1998b, 2000).

Presentation in the mid-trimester has until recently been associated with an 80–100% perinatal loss rate, either from preterm delivery secondary to polyhydramnios or from IUD following severe growth restriction or circulatory overload (Weir et al. 1979; Gonsoulin et al. 1990). The majority of cases complicated by TTTS have estimated fetal weight discordance in utero, and differences of <15% are unusual (Fisk et al. 1990a). There is some evidence that the prognosis worsens with an increasing difference in abdominal circumference measurements (Saunders et al. 1992), cumulatively reflecting the severity of overload/early hydrops in the recipient and growth restriction in the donor.

TTTS presents in the second trimester with discordant amniotic fluid volume (Fig. 9.13) (Duncan et al. 1997). The donor twin becomes oliguric, with consequent oligohydramnios, hence appearing enshrouded within its membrane and finally stuck to the uterine wall. In addition, neither the urinary bladder nor the stomach is usually visible, once anhydramnios is present. The growth velocity of the donor may follow the asymmetrical pattern seen with fetuses

affected by FGR. Furthermore, it may also exhibit abnormal umbilical and MCA velocities, with absent/reversed flow in the former and redistribution in the latter (Hecher et al. 1995b).

The overloaded recipient develops polyuria and severe polyhydramnios. The degree of polyhydramnios cannot be solely explained by the transfusion of blood volume from the donor to the recipient, and there are emerging data implicating alterations in the renin–angiotensin system resulting in the polyhydramnios/oligohydramnios sequence (Mahieu-Caputo et al. 2001).

Venous Doppler studies in the recipient fetus deteriorate in accordance with the disease process. There may be evidence of pulsatile venous flow, progressing to reverse EDF within the ductus venosus (Hecher et al. 1995c). The development of tricuspid regurgitation indicates worsening of the right-sided cardiac failure. The recipient fetus may develop hydrops, the mechanism of which has been assumed to be volume overload. Doppler studies have shown that severe cases are often associated with venous waveform patterns consistent with raised central venous pressure (Rizzo et al. 1994; Hecher et al. 1995c). Typically, recipient fetuses with cardiac dysfunction develop cardiomegaly, tricuspid regurgitation, ventricular hypertrophy and, ultimately, right ventricular outflow tract obstruction (Zosmer et al. 1994).

A number of groups have attempted to ‘stage’ TTTS in an attempt to rationalise treatment (Quintero et al. 1999; Taylor et al. 2000). Several prognostic criteria have been used, including arterial and venous Doppler studies, fetal size discordancy, bladder dynamics and amniotic fluid volume. However, sudden unpredictable deterioration in clinical condition can still occur.

Therapeutic options for TTTS

A variety of treatments, including transplacental drug therapy, selective fetocide, AR, laser ablation (LA) of the intertwin placental anastomoses, and intrauterine venesection and exchange transfusion, have been attempted, with varying degrees of success. Current treatment mainly involves the use of AR, LA and selective fetocide, alone or in combination according to disease severity and progression.

Serial amnioreduction

Serial AR remains the simplest of treatment options, with at least one fetus surviving (at 4 weeks postnatal age) in 71% of pregnancies (Mari et al. 2001). Although AR aims primarily to control polyhydramnios to allow prolongation of gestation, there is some evidence in TTTS that it may ameliorate fetal condition and the disease process. AR was associated with a 74% median increase in uterine blood flow in one study (Bower et al. 1995), while others have demonstrated that fetal MCA pulsatility indices fell acutely with AR in both recipient and donor fetuses (Mari et al. 1992).

Until recently, serial aggressive AR was the mainstay of management of this condition. However, because of the high rates of perinatal mortality and morbidity and that no attempt was being made to affect the disease process itself, other techniques have been developed.

Laser ablation

The technique of LA of placental vessels was first developed in animals in 1985 (de Lia et al. 1985) and later applied to human pregnancies with TTTS (de Lia et al. 1995; Ville et al. 1995). The initial technique involved the photocoagulation of all surface chorionic vessels crossing the interwin septum with a neodymium:yttrium–aluminium–garnet (Nd:YAG) laser. The early results were disappointing, with perinatal survival similar to that of AR (de Lia et al. 1995; Ville et al. 1995). The high procedure-related loss rates

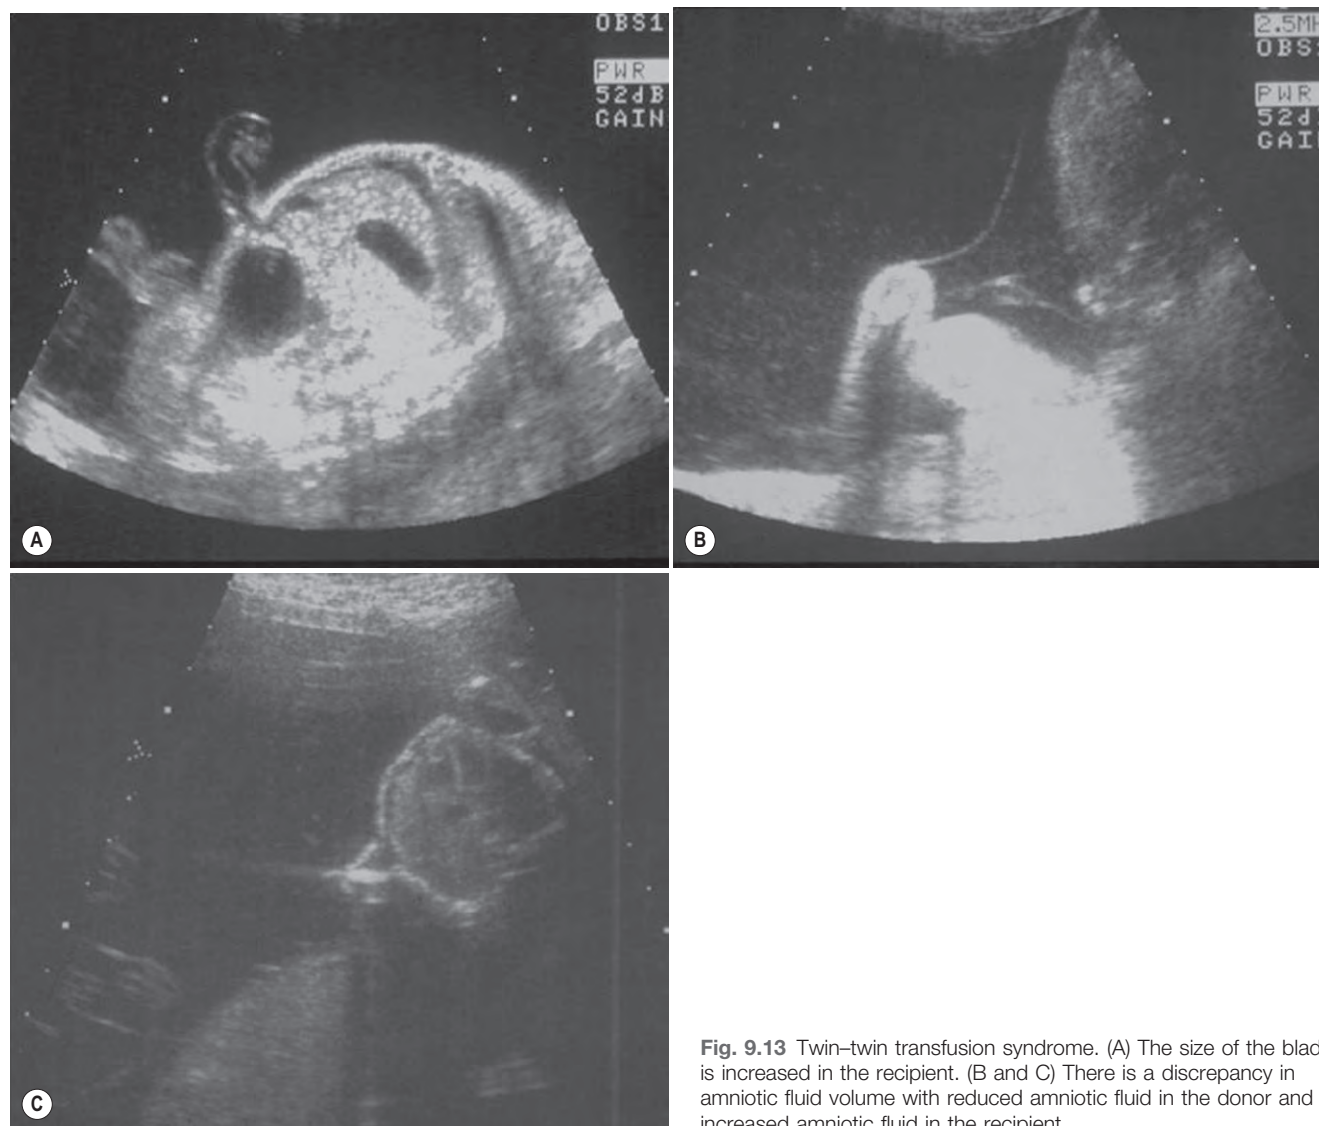

Fig. 9.13 Twin–twin transfusion syndrome. (A) The size of the bladder is increased in the recipient. (B and C) There is a discrepancy in amniotic fluid volume with reduced amniotic fluid in the donor and increased amniotic fluid in the recipient.

were attributed to the unnecessary destruction of viable placental tissue using such a non-selective technique.

However, with refinement of the technique and increased operator experience, rates for survival of at least one twin have improved to 75% (Eurofetus 2003). Now, most operators perform targeted ablation, with selection and ablation of confirmed anastomoses, while leaving viable placental tissue untouched.

Selective fetocide

Selective fetocide has been suggested to have a role in the management of TTTS by a number of groups. In its favour, the procedure may be performed once the IUD of one of the twins appears imminent, or once all other treatment options have failed. Indeed, this usually allows the parents to feel that the procedure is absolutely necessary to allow even a single twin to be saved. However, this delay may allow some degree of insult to happen to the surviving fetus, before its co-twin is terminated. Either the donor or the recipient fetus may become preterminal, and, in order to be a safe and effective procedure, the possibility of acute transfusion of the remaining twin into the terminated twin must be avoided (see below).

Management of TTTS

Most clinicians treat pregnancies complicated by TTTS on a case-by-case basis. First, disease severity is assessed by staging; thereafter, management is contentious. A Cochrane review in 2008 has provided some clarity. Perinatal outcomes were evaluated in one RCT of septostomy versus serial AR and two RCTs comparing LA with serial AR (Roberts et al. 2008). There were no differences in the incidence of one or more fetal deaths between septostomy and AR (Moise et al. 2003). LA was associated with lower rates of perinatal (relative risk 0.59, 95% CI 0.40–0.87) and neonatal (relative risk 0.29, 95% CI 0.14–0.61) death (Roberts et al. 2008). The larger of the two studies in this review, the Eurofetus study, consisted mainly of twins with moderate to severe disease. Severity of TTTS is commonly graded by the Quintero staging system (Ch. 23) (Quintero 1999). In the Eurofetus study there were only 11 twins with stage 1 TTTS. In this group there remains an equipoise on the appropriate management of these cases. Subgroup analysis suggested greater benefit of laser with earlier disease. However, this is a post hoc analysis and the results must be interpreted with caution. Some observational data suggest the majority of these mild cases do not

progress and AR may be associated with higher perinatal survival rates (Fisk et al. 2009). There is a need for RCTs in the management of these mild cases.

Neurological outcome

There are emerging data regarding the longer term sequelae of TTTS. Cerebral white-matter lesions are increased in monochorionic twin pregnancies overall, both with and without TTTS, and this has been attributed to haemodynamic imbalance due to the shared circulation (Bejar et al. 1990). However, in surviving twins from pregnancies complicated by severe TTTS and managed by AR, the incidence of antenatally acquired neurological lesions was found to be 35%, although, with the exception of one case, these lesions were relatively subtle, and thus of uncertain long-term significance (Denbow et al. 1998a). Both donors and recipients were shown to be at risk, although the aetiology of the damage is uncertain. It has been speculated that in the recipient the raised haematocrit, and hence potential for intravascular sludging, leads to cortical damage, with the donor's neurological injury secondary to anaemia. However, large differences in fetal Hb concentrations in utero are uncommon (Denbow et al. 1998c). It has been shown that LA, rather than AR, reduces the incidence of cerebral palsy in survivors (4.2% versus 24.4%) because the disease process is largely arrested at the time of treatment (Quintero et al. 2003); however this has yet to be substantiated in an RCT. Follow-up data from surviving infants in the Eurofetus trial failed to demonstrate a difference in neurodevelopment at 2 years of age between twins treated by AR compared with LA (Örtqvist et al. 2008).

Acute interfetal transfusion

Following the IUD of one of a monochorionic twin pair, there is approximately a 25% incidence of necrotic brain and/or renal lesions (increasing to 50% if the pregnancy was complicated by TTTS) and a similar risk of IUD in the otherwise healthy co-twin (Fusi and Gordon 1990; van Heteren et al. 1998). The aetiology of this insult appears to be haemodynamic. An imbalance in interfetal transfusion following the death of one twin in utero gives rise to a period of hypotension, potentially resulting in ischaemia, as the initially healthy twin transfuses blood into the dead twin's circulation (Fusi et al. 1991). The phenomenon of acute interfetal transfusion also has implications in pregnancies where selective fetocide is indicated, e.g. discordant fetal anomaly, TTTS in extremis, and twin reversed arterial perfusion sequence.

Selective fetocide ideally should involve an occlusive technique, to prevent any residual possibility of the surviving twin exsanguinating into the non-viable twin's circulation. After initial reports of ultrasound-guided techniques, including vascular occlusion with absolute alcohol (Denbow et al. 1997), histoacryl gel injection (Dommergues et al. 1995) or thrombogenic coils (Bebbington et al. 1995), it subsequently became clear that success rates were poor, resulting in co-twin death or damage (Denbow et al. 1999; Nicolini et al. 2001). Now, cord occlusion is performed with bipolar diathermy, with co-twin survival (taking into account pre-existing morbidity) of 76%. Serial ultrasound or MRI on the surviving twin's brain is recommended to look for evidence of cortical damage.

Multifetal pregnancy reduction and selective fetocide in dichorionic twins

Multifetal pregnancy reduction

This procedure aims to obviate the daunting perinatal mortality in high-order multiple pregnancies (more than three fetuses) by reducing fetal numbers to a twin or triplet gestation with improved

perinatal outcome. In non-reduced higher order (more than three fetuses) pregnancies, approximately one-third will miscarry prior to 24 weeks (Evans et al. 2002).

The initial approach, which involved transvaginal aspiration, has been abandoned in view of high loss rates (Itskowitz et al. 1989) and all are now done by transabdominal injection of KCl into the fetal thorax (Berkowitz et al. 1988; Evans et al. 1988). Most such pregnancies are the result of overzealous use of ovulation induction agents and are therefore usually multizygotic and multichorionic, although not always in twins (Wenstrom et al. 1993). The procedure is best delayed until 10–12 weeks, when the risks of abortion and spontaneous regression have subsided and the NT can be measured. The optimal number of fetuses to be left remains controversial, but most centres reduce to twins. The chief risk, that of complete abortion of all fetuses, varies around 4–16% and is influenced by the starting number (triplets 4.5%, quadruplets 8%, quintuplets 11%) and the finishing number after the reduction (ideally two), together with operator experience (Evans et al. 2003).

Trichorionic triplets pose the hardest decision in terms of consideration of multifetal pregnancy reduction. One series compared the outcome of reduced trichorionic triplets with that of those managed expectantly (Papageorghiou et al. 2002). Although the rate of miscarriage in the reduced group was higher (8.3% versus 3.2%), the rate of preterm delivery was considerably lower (9.8% versus 23.1%). Overall, the non-reduced pregnancies had a higher chance of survival (93.3% versus 90.3%) but at the cost of a higher estimated incidence of handicap (1.5% versus 0.6% per fetus).

Selective fetocide

In twin pregnancies discordant for fetal anomaly, selective termination of the affected fetus is an option. Intracardiac KCl injection is the recommended technique (Isada et al. 1992), except in monochorionic pregnancies because of the risk of acute interfetal transfusion. In the 20% of cases concordant for fetal sex with a single placental mass on ultrasound, determination of chorionicity will require careful evaluation of the membranous septum. This requires evaluation of the septal thickness and the presence or absence of the lambda sign (Fig. 9.14) (Finberg 1992). A septum that is 0.2 mm thick and/or contains three or four layers strongly suggests dichorionic placentation (Barss et al. 1985; D'Alton and Dudley 1989), although the reproducibility and hence the usefulness of this measurement has been shown to be poor after the first trimester (Stagiannis et al. 1995). A combination of all the signs should provide more than 90% accuracy in chorionicity determination in the second trimester (Scardo et al. 1995), but 100% accuracy in the first trimester (Monteagudo et al. 1994; Carroll et al. 2002). One series indicated an overall loss rate of 4% (2.4% in twins, 12.5% in triplets) following selective fetocide (Eddelman et al. 2002), with over 80% of deliveries occurring beyond 32 weeks' gestation. Loss rates are lower if the procedure is performed before 16 weeks (Evans et al. 1994).

Fetal surgery

In several congenital malformations, a satisfactory outcome is often achieved with postnatal surgical correction. In some, however, the uncorrected malformation results in progressive organ damage in utero, jeopardising survival. There may be a role in such conditions for in utero intervention. Initial attempts at fetal surgery took one of two forms: open surgical correction at hysterotomy, or bypassing obstructive lesions by ultrasound-guided insertion of catheter shunts (Fig. 9.15). More recently there has been increasing interest in endoscopic surgical techniques, resulting in lowered maternal morbidity.

Fig. 9.14 Transvaginal ultrasound view of first-trimester (A) monochorionic and (B) dichorionic twin gestations, showing the amnions and chorions before fusion. (Reproduced from the RCOG Press.)

Fig. 9.15 Pleuroamniotic shunting. (A) The trocar and cannula are inserted transamniotically into the effusion. The guidewire is then straightened, the double-pigtail catheter inserted into the cannula and the wire removed. (B) A short introducer rod then deposits half the catheter within the hemithorax. (C) The cannula is then withdrawn into the amniotic cavity, and a long introducer rod is inserted to position the other half of the shunt in the amniotic cavity. H, heart; S, spine; L, lungs. (Reproduced from Rodeck et al. (1988).)

These techniques should only be contemplated in centres with expertise, and for conditions in which animal models have demonstrated benefit from correction in utero. Unfortunately, the overall results for open fetal surgery have been disappointing. Despite being limited to a few very specialised centres, the problem of inexorable preterm labour subsequent to surgery has limited the enthusiasm for the approach. If fetal surgery is to be considered in the future, it is essential that chromosomal and other structural malformations first be excluded. Moreover, reliable antenatal predictors are needed when selecting cases for intervention, so that fetal surgery is withheld from those which would otherwise have a satisfactory outcome, and from those in which the pathology is irreversible.

Intrathoracic lesions

Diaphragmatic hernia (Ch. 27.6)

The mortality rate from diaphragmatic hernia diagnosed in utero remains high at 75% despite optimal postnatal care (Adzick et al. 1985b; Harrison et al. 1990). The main determinant of outcome is the degree of pulmonary hypoplasia resulting from in utero lung compression, dependent on the timing and volume of visceral herniation through the diaphragm. Predictors of perinatal loss include earlier gestational age at diagnosis, lung area to head circumference ratio (LHR) of less than 1, herniation of the liver into the thoracic cavity and gestational age at delivery (Jani et al. 2007; Worley et al. 2009). Increasingly, fetal MRI is also used to quantify the volume

of herniation and estimation of LHR and fetal lung volume (Jani et al. 2008; Kilian et al. 2009; Worley et al. 2009). A recent study using fetal MRI found neonatal mortality rates of 86% in cases where the fetal liver occupied more than 20% of the fetal thorax compared with 13% in cases with lower volumes of herniation (Worley et al. 2009). MRI was also found to have slightly better prognostic accuracy in the assessment of pulmonary hypoplasia and the prediction of neonatal outcome than sonographic assessments (Kilian et al. 2009).

An alternative, less invasive, corrective approach to diaphragmatic hernia is tracheal ligation. The underlying theory is that preventing drainage of lung liquid will allow the lung to grow (PLUG – plug the lung until it grows), and animal experiments have confirmed this hypothesis (Harrison et al. 1993; Wilson et al. 1993). Open tracheal ligation, unfortunately, still carries the risk of preterm labour, and may also result in tracheal stenosis. The recent development of endoscopic techniques (e.g. FETO) for insertion of a temporary tracheal plug looks promising, (Flake et al. 2000; Harrison et al. 2001) but much work needs to be done on the optimal timing, duration and method for FETO before it can be introduced into clinical practice.

In a recent series of 210 cases, the success rate of tracheal occlusion was approximately 97%. The entry criteria of the study were severe congenital diaphragmatic hernia on the basis of intrathoracic herniation of the liver and LHR of less than 1 (Jani et al. 2009). The survival rate was 49% and 35% for isolated left- and right-sided congenital diaphragmatic hernias respectively. Approximately 10% of all deaths were related to the removal of the balloon used for occlusion. When compared with historical data on those managed expectantly, the survival rates increased from 24% to 49% for left-sided lesions and from 0% to 35% in right-sided lesions. However, only RCTs will provide the definitive benefit associated with this procedure. An RCT from the USA was recently abandoned because of the high rates of survival in the control arm of the trial, resulting in there being no difference in survival rates between both arms of the study (Harrison et al. 2003). Because the tracheal balloon needs to be removed or decompressed prior to delivery, ongoing perinatal management is essential; serious complications have been reported (Jani et al. 2009).

Fetal hydrothorax

Perinatal mortality in fetal hydrothorax exceeds 50%, and is higher when associated with hydrops than in isolation (Roberts et al. 1986; Castillo et al. 1987). Compression of the lung during its canalicular phase (17–24 weeks) produces pulmonary hypoplasia, whereas large effusions cause polyhydramnios by impairing swallowing, and hydrops by vena caval obstruction and cardiac compression (Benacerraf and Frigoletto 1985). Chylothorax, the commonest cause in neonates, is diagnosed after alimentation by demonstrating chylomicrons in pleural fluid (Chernick and Reed 1970). The diagnosis may also be made in the fetus by showing high lymphocyte cell counts in aspirated pleural fluid (Elser et al. 1983; Benacerraf et al. 1986b).

Ultrasound-guided aspiration of fetal hydrothoraces facilitates neonatal resuscitation if performed immediately prior to delivery (Schmidt et al. 1985). Because the fluid reaccumulates within 6–48 hours (Petres et al. 1982; Nicolaides et al. 1985a), long-term drainage is required. This is achieved by a plastic pleuroamniotic shunt, inserted under ultrasound guidance (Fig. 9.15). In three series totalling 34 patients (Rodeck et al. 1988; Longaker et al. 1989; Nicolaides and Azar 1990), resolution was achieved in 17 (50%) patients, 16 (94%) of whom survived, with no respiratory complications. Only two infants survived when hydrops persisted (12%).

A single aspiration is performed 1 week beforehand, as the effusion does not always reaccumulate (Benacerraf and Frigoletto 1985; Benacerraf et al. 1986b), especially with small or unilateral effusions. In fetal hydrothoraces unassociated with other abnormalities, shunting is indicated in the presence of hydrops or polyhydramnios, or if detected in mid-trimester. The catheters should be clamped immediately at delivery to prevent a pneumothorax; alternatively, the neonate should be electively intubated and ventilated.

Cystic adenomatoid malformation of the lung (Ch. 27.5)

This rare malformation may result in pulmonary hypoplasia, hydrops and perinatal death in a small percentage of cases (Adzick et al. 1985a). The solid type of lesion is more likely to be associated with a poor prognosis than is the macrocystic lesion, where cysts can be visualised on ultrasound. In the macrocystic type of lesion, long-term drainage of a solitary intrathoracic cyst can be performed, resulting in good outcome at birth (Nicolaides et al. 1987a). The San Francisco group has also shown that, with severe CCAM associated with hydrops, a combination that carries an extremely poor prognosis, open fetal surgical resection by lobectomy offers a good chance of survival. Lobectomy of the massively enlarged pulmonary lobe was performed between 21 and 27 weeks' gestation in eight fetuses, resulting in five survivors (Adzick et al. 1993). This is therefore one of the conditions where fetal surgery may have a role, although it should only be embarked upon in those cases which otherwise would have an extremely poor outlook.

Obstructive uropathy

Posterior urethral valves (Ch. 35.2)

In fetuses with PUVs unassociated with other anomalies, the two main factors determining perinatal outcome are pulmonary hypoplasia and renal dysplasia (Harrison et al. 1982; Nakayama et al. 1986), which seem related to the duration and severity of obstruction. Lack of a urinary contribution to amniotic fluid in the mid-trimester leads to pulmonary hypoplasia. Although its pathogenesis is not understood (Nicolini et al. 1989a), numerous animal and human studies indicate that lung hypoplasia is a consequence of oligohydramnios. Urethral obstruction has also been considered responsible for renal dysplasia, presumably mediated by raised urinary pressure (Harrison et al. 1981; Kurth et al. 1981). However, intravesical pressure seems only marginally raised in fetuses with low obstructive uropathies (Nicolini et al. 1991). There is an alternative embryological theory, which suggests that renal dysplasia is not secondary to PUVs but results from the same early defect, resulting in abnormal interaction between the urethral bud and the metanephrogenic mesenchyme (Berman and Maizels 1982; Stephens 1983).

As the surgical correction of PUVs is relatively simple postnatally, a hypothesis emerged that bypass of the obstruction in utero would minimise renal dysplasia and restore amniotic fluid, thereby preventing pulmonary hypoplasia and allowing survival at birth (Harrison et al. 1981). The basis for such intervention was rigorously tested in animals. Urinary obstruction in fetal lambs produces both renal dysplasia and lung hypoplasia (Glick et al. 1983; Harrison et al. 1983), whereas early decompression prevents these sequelae (Harrison et al. 1982; Glick et al. 1984).

The presence of a normal amniotic fluid volume indicates that lung hypoplasia will not occur, that the obstruction is incomplete and that the kidneys are producing adequate amounts of urine. Therefore, any benefit from bypass procedures needs to be restricted

to those fetuses with severe oligohydramnios, in whom irreversible renal damage has not yet developed. Vesicoamniotic shunting of a fetus with severe renal dysplasia would not only fail to prevent neonatal renal failure, but would also fail to prevent pulmonary hypoplasia if the kidneys in utero were unable to restore amniotic fluid volume. Accordingly, accurate prediction of fetal renal function is important in selecting potential cases for intrauterine surgery. Although renal cysts are visualised in only 44% of dysplastic kidneys, their presence strongly suggests dysplasia (Mahoney et al. 1984). Hyperechogenicity of the renal parenchyma predicts dysplasia with a sensitivity of 73% and a specificity of 80% (Mahoney et al. 1984).

In view of the inaccuracy of ultrasound in predicting renal function, other methods have been sought. Biochemical analysis of fetal urine for the prediction of later renal function has been thought to be useful by some (Glick et al. 1985; Grannum et al. 1989) but not by others (Weiner et al. 1986; Wilkins et al. 1987). Initially, threshold values to define an isotonic urine with probable poor outcome, Na^+ 0.100 mEq/l, Cl^- 0.90 mEq/l and osmolality 0.210 mmol/l, were used. Refinements have been made by providing normal values for electrolytes (Na^+ and Cl^-) with gestation between 16 and 33 weeks (Nicolini et al. 1992) and by serial sampling, which may provide more accurate information (Johnson et al. 1994). Others have suggested that urinary microproteins may be useful indicators of renal damage, in particular urinary (Mandelbrot et al. 1991; Lipitz et al. 1993; Muller et al. 1993), and possibly fetal, serum β_2 -microglobulin (Berry et al. 1995). In present practice a decision whether to shunt or not is based on a combination of urinary electrolytes, β_2 -microglobulin, the appearance of the renal tract on ultrasound and on bladder and liquor volumes.

The standard method of vesicoamniotic shunting is by ultrasound-guided insertion of an indwelling plastic double-pigtail catheter (Harrison et al. 1982; Manning et al. 1986), as for pleuroamniotic shunting. The results of 73 cases of shunting procedures for low obstructive uropathy reported to the International Registry were not encouraging, with only a 41% perinatal survival rate (Manning et al. 1986). However, this included fetuses with pathologies other than PUVs, with chromosomal and other abnormalities, and with normal amniotic fluid volume, and 70% of the contributing centres had had experience of only one case. Most of the scepticism about this procedure (Elder et al. 1987; Reuss et al. 1988) may thus be attributed to poor case selection.

It appears, therefore, that inclusion criteria should be rigorously applied to restrict shunting to those few fetuses in which it may be of benefit, i.e. otherwise normal euploid fetuses with sonographically 'normal' kidneys, with severe oligohydramnios and biochemical evidence of adequate renal function.

The long-term outcome following vesicoamniotic shunting is somewhat better when all obstructive uropathies (e.g. prune-belly syndrome, urethral atresia, vesicoureteral reflux) are considered (Freedman et al. 1999). At 2-year follow-up of the 62% of fetuses that survived, one-third had undergone renal transplantation for renal failure, with a further 21% having renal impairment; the remaining 43% had normal renal function. Only 50% were acceptably continent at follow-up.

Most of the studies on fetal intervention have been observational studies. A systematic review failed to identify any RCT on fetal bladder shunting (Clark et al. 2003). Meta-analysis of the non-randomised observational studies suggests an improvement in perinatal survival associated with shunting, especially in fetuses with poor predicted outcome. However, this is an invasive procedure associated with both maternal morbidity and risk of miscarriage or preterm labour. Currently in the UK, the PLUTO trial, a multicentre RCT, aims to provide conclusive evidence on the benefit of

vesicoamniotic shunting compared with expectant management. The study outcomes include rates of perinatal survival and fetal renal function at 4–6 weeks following birth and at 12 months of life (Zaccara et al. 2005; The PLUTO Collaborative Study Group 2007). We currently await the findings of this study.

Other surgical conditions

Hydrocephalus (Ch. 40.8 and Ch. 40.5)

Obstruction of the aqueduct of Sylvius causes a rise in cerebrospinal fluid pressure, ventricular enlargement, cortical thinning and irreversible neurological damage. As ventricular shunting in the neonatal period dramatically improves outcome (Laurence and Coates 1962), and as ventriculomegaly may progress in utero, the hypothesis emerged that intrauterine decompression of fetal hydrocephalus would prevent neurological damage. Although initial work in a primate model suggested that in utero shunting improved survival and outcome (Michejda and Hodgen 1981), reports to the International Registry (Manning et al. 1986) demonstrated that in utero shunting in human fetuses resulted in increased survival of severely handicapped infants, and therefore the technique has been abandoned.

Sacroccocygeal teratoma (Ch. 36 and Ch. 29.4)

Congenital sacroccocygeal teratomas are usually benign and in the neonatal period are associated with good outcome after surgical resection. When they are diagnosed in the mid-trimester, however, hydrops frequently develops secondary to cardiac failure from arteriovenous shunting, indicating impending fetal demise (Flake et al. 1986). One group has reported success with in utero open surgical resection of the tumour (Adzick et al. 1993), although their previous more problematic experience had suggested that resection must take place before the initiation of end-stage cardiac failure in the fetus and the hydropic placenta, leading to the maternal 'mirror syndrome' (Langer et al. 1989; Adzick et al. 1997).

Alternative therapies include cytorreduction of the tumour mass by ablative techniques, thereby reducing the venous steal and hence risk of high-output cardiac failure. Several thermocoagulative techniques have been employed, with only limited success rates reported (Paek et al. 2001).

Neural tube defects (Ch. 40.8)

There is growing experience with in utero closure of NTDs. An experimental model of spina bifida in the sheep suggests that in utero correction of the spinal defect can prevent the neurological dysfunction normally seen at birth (Meuli et al. 1995). Results in humans have been less impressive, although a substantial reduction in shunt-dependent hydrocephalus was demonstrated in one series (Tulipan et al. 2003). It is also clear that in utero therapy has no benefit with lesions higher in the fetal spine (above L3) and gestations greater than 25 weeks. The Management of Myelomeningocele Study (MOMS) aims to compare in utero surgery with postnatal surgery. This RCT in the USA is currently still in the recruitment phase.

Fetal valvuloplasty

There have been several reports of treatment of valve atresia in utero. In one report, two fetuses with complete or almost complete pulmonary atresia and imminent hydrops underwent pulmonary valvuloplasty in utero at mid-gestation (Tulzer et al. 2002). Both

children (one aged 18 months and one aged 12 months) now have biventricular circulation. In a larger series of cases with severe aortic stenosis at risk of hypoplastic left heart syndrome, growth of the left heart structures was maintained following fetal valvulopalsty

(Tworetzky et al. 2004). As with other fetal surgeries, further research and experience are necessary before this becomes standard practice.

Introduction and definitions

A fetus is defined, antenatally, as small for gestational age (SGA) when its estimated fetal weight (EFW) is below a specified percentile for its gestation, for a given population. Thus, SGA is a statistical concept, based on the distribution of EFW within a population. The World Health Organization (WHO) has chosen the 10th percentile as an arbitrary threshold for identifying SGA (WHO 1995). Another commonly used threshold is the total population mean EFW minus two standard deviations of a population-based growth curve (i.e. setting the normal range for growth as roughly between the 2.5th and the 97.5th percentile) (Marsal et al. 1996). Babies defined as SGA using the 10th percentile threshold have a higher rate of adverse outcome than average-for-gestational-age babies (De Jong et al. 1998; McIntire et al. 1999). However, not all fetuses with SGA have an abnormal pattern of growth. In reality, up to 70% of fetuses identified as SGA are 'constitutionally small' and healthy, while the remainder have intrauterine growth restriction (IUGR) with abnormal growth velocity and increased risk of adverse outcome (Manning et al. 1981; Patterson and Pouliot 1987; Lin and Santolaya-Forgas 1998).

A fetus with IUGR is one that has failed to achieve its genetically determined growth potential, owing to one or more pathological factors (Table 10.1). In comparison with a normally grown fetus with no structural or chromosomal defect, an IUGR fetus has at least a 10-fold increased risk of perinatal mortality (McIntire et al. 1999; Regev et al. 2003). In the developed world, IUGR is the commonest cause of stillbirth and the second leading cause of perinatal mortality, after preterm birth. A significant proportion of IUGR fetuses are not detected before birth and recent reports show that undiagnosed IUGR was a factor in over 50% of stillbirths in the UK (Confidential Enquiry into Maternal and Child Health 2007).

There are many reasons why IUGR poses a major challenge to clinicians and researchers. The aetiology of IUGR is heterogeneous with multiple causal pathways, and there is no proven therapy. The most effective intervention is delivery, thus many clinicians advocate early intervention for suspected IUGR. However, it is important to distinguish between a constitutionally small fetus from one that is IUGR, in order to avoid iatrogenic morbidity to the mother and baby due to unnecessary operative and/or preterm delivery. Central to this problem is the lack of standard definitions or uniform diagnostic criteria for IUGR. Consequently, many researchers have used the definitions for SGA and IUGR interchangeably, and

Table 10.1 Risk factors for intrauterine growth restriction

Fetal	<p>Chromosomal anomaly: triploidy, trisomies (21,18,13), Turner syndrome, uniparental disomy, confined placental mosaicism</p> <p>Structural malformation: cardiac malformations, neural tube defects, gastroschisis, diaphragmatic hernia, renal agenesis, multiple malformations</p> <p>Genetic abnormalities and syndromes: Bloom, Brachmann-de Lange, Cornelia de Lange, De Sanctis-Cachione, Donohue, Dubowitz, Fanconi, Johanson-Blizzard, Mulibrey nanism, osteochondrodysplasias, Prader-Willi, Roberts, Russell-Silver, Rubenstein-Taybi, Seckel, Williams-Beuren</p> <p>Fetal infections: cytomegalovirus, toxoplasmosis, rubella, malaria, human immunodeficiency virus, varicella-zoster, herpes simplex, Epstein-Barr virus, congenital tertiary syphilis</p> <p>Multiple pregnancies: monochorionic gestation, twin-to-twin transfusion</p>
Maternal	<p>Past obstetric history: previous intrauterine growth restriction, stillbirth, preterm birth</p> <p>Social/environmental/nutritional: extreme reproductive age, short interpregnancy interval, poor diet, anorexia nervosa, body mass index <20, active inflammatory bowel disease, smoking, substance abuse (alcohol, cocaine, opiates, amphetamines), self-neglect and/or psychiatric illness, medication (β-blockers, overtreatment of hypertension), high altitude</p> <p>Vasculopathy: chronic hypertension, pre-eclampsia, diabetes mellitus, sickle-cell disease, antiphospholipid syndrome, systemic lupus erythematosus</p> <p>Renal disease: glomerulonephritis, lupus nephritis, chronic renal failure</p> <p>Thrombophilia: factor V Leiden G1691A, prothrombin G20210A</p> <p>Hypoxia: severe anaemia, chronic lung disease, severe asthma, cyanotic heart disease</p> <p>Reduced plasma volume expansion</p>
Placenta	<p>Abnormalities of the umbilical cord: single umbilical artery, velamentous insertion of the cord, overcoiled umbilical cord</p> <p>Tumours: chorioangiomas, placental mesenchymal dysplasia</p> <p>Vascular: vascular malformations, fetal thrombotic vasculopathy, placental abruption</p> <p>Abnormal placental development: abnormal trophoblast invasion, recurrent bleeding, placenta praevia, circumvallate placenta, confined placental mosaicism</p>
Uterine	Uterine abnormality, uterine fibroids, assisted reproductive techniques
Endocrine factors	Vascular endothelial growth factor, placental growth factor, fms-like tyrosine kinase 1, pregnancy-associated plasma protein A, insulin-like growth factor

used different thresholds to identify the normal range for growth. This has led to classification bias and difficulties in interpreting findings from IUGR studies. In essence, the use of a 10th percentile threshold alone fails to identify IUGR fetuses with abnormal growth pattern but whose EFW is above the threshold value (Marconi et al. 2008).

To improve the identification of SGA fetuses with adverse outcomes, the 10th percentile threshold of a 'standard' or 'healthy obstetric population' with low-risk pregnancies and normal perinatal outcome should be used instead of a growth curve based on the entire obstetric population (Ferdynus et al. 2009). In addition, since IUGR is more common in babies born preterm, the growth standard should be ultrasound-based fetal weight reference rather than neonatal birthweight reference (Bukowski et al. 2001). The use of a growth standard that takes into account biological variation in fetal size due to fetal gender, ethnicity, maternal size and parity, or a 'customised growth standard', also improves the antenatal detection of SGA fetuses with adverse outcomes (Mongelli and Gardosi 1996; Figueras et al. 2007). Defining a fetus as SGA using both the population-based and the customised standard was associated with a fivefold increase in the detection rate of fetuses with adverse outcomes (Zhang et al. 2007). However, in reality, the use of a customised growth standard is limited by a number of factors: (1) a large pregnancy database with sufficient numbers of normal pregnancies with different biological characteristics, mentioned above, is required to create an accurate customised growth standard; (2) fetal gender cannot always be identified accurately by ultrasonography, and, even when this is correctly identified, the parents may not want

this information to be revealed; and (3) the customised growth standard may be less accurate for fetuses of mixed heritage. After birth, IUGR can be confirmed in a newborn by measuring an index of body mass or malnutrition, known as neonatal ponderal index. This is calculated as $(\text{birthweight (g)}/\text{height (cm)}^3) \times 100$. A ponderal index below the 10th percentile is more closely associated with adverse perinatal outcome than birthweight alone (Walther and Ramaekers 1982; WHO 1995).

Incidence and recurrence rate

Using the 10th percentile threshold, at least 10% of singleton pregnancies will be labelled as SGA. The incidence of SGA is higher in multiple pregnancies, with approximately 20% of dichorionic and 30% of monochorionic twins being categorised as SGA (Klam et al. 2005). The true incidence of IUGR in the general obstetric population is likely to be underestimated since it is often undetected. For example, it is found that approximately 30% of babies born before 35 weeks of gestation were below the 10th percentile for gestational age compared with 4.5% of babies born at term (37 or more weeks of gestation) (Bukowski et al. 2001). Thus, the incidence of SGA is six times higher in babies born preterm than in those born at term. IUGR occurs in 30–40% of pregnancies affected by pre-eclampsia (Walker 2000). In women who had a previous IUGR pregnancy, the recurrence rate is about 20% (Patterson et al. 1986). However, this is increased to approximately 50% in women with previous early IUGR (before 34 weeks of gestation), with a highest recurrence risk

Table 10.2 Consequences of intrauterine growth restriction

INTRAPARTUM	NEONATAL	LONG-TERM	ADULTHOOD
Fetal death	Hypoxic–ischaemic encephalopathy	Bronchopulmonary dysplasia	Diabetes

in women with pre-existing renal disease and superimposed pre-eclampsia.

The aetiology of IUGR

The consequences of IUGR are shown in Table 10.2. Normal fetal growth requires both a normal fetus and an adequate supply of substrates (i.e. oxygen and nutrients) from the maternal circulation into the fetal circulation via the placenta. The latter depends on adequate levels of substrates within the maternal circulation, adequate maternal blood flow to the placenta, and a normally functioning placenta. It was initially thought that about 80–90% of IUGR was caused by problems with the supply of substrates while an intrinsic fetal factor is the cause of a further 15–20% of cases. However, recent investigations have shown that normal endocrine signalling also plays an important role in the control and regulation of fetal and placental growth.

Factors affecting fetal growth potential (IUGR of fetal origin)

Chromosomal abnormalities, especially triploidy and trisomies 13, 18 and 21, are responsible for about 7% of fetuses with IUGR; however this figure is as high as 19% in tertiary referral centres (Snijders et al. 1993). Structural abnormalities are responsible for about 10–20% of IUGR. Genetic abnormalities and syndromes are commonly associated with IUGR. Congenital infections account for about 5% of IUGR cases (Pearce and Robinson 1995). IUGR is more common if fetal infection occurs early in pregnancy. Common causes of fetal infection in the developed world include cytomegalovirus and toxoplasmosis, with rubella occurring less often owing to vaccination. Common causes of fetal infections in the developing world include malaria, which accounts for up to 70% of SGA babies

in endemic areas of sub-Saharan Africa (Steketee et al. 2001), and congenital human immunodeficiency virus (HIV) infection due to maternal-to-child transmission in utero.

Multiple pregnancies are associated with a high incidence of IUGR, especially in monochorionic or higher order gestations. A growth discordance of 15% or more occurs in up to 30% of twin pregnancies and this can be used as a marker for IUGR; however, both twins can be affected (Fieni and Gramelli 2004; Klam et al. 2005). This has been attributed to ‘uterine overcrowding’. Chorionicity is the most important determinant of perinatal and long-term outcomes. There is a higher incidence of chromosomal and structural abnormalities associated with monochorionicity; problems specific to twinning are discussed in Chapter 23 (Fick et al. 2006).

Factors leading to substrate deprivation (IUGR of maternal origin)

Fetal deprivation of nutrition or oxygen may unusually occur as a consequence of maternal undernutrition. This is associated with anorexia nervosa, body mass index less than 20 (Naeye et al. 1973; Godfrey et al. 1996; Conti et al. 1998), substance abuse and self-neglect, including smoking, moderate to high alcohol intake, cocaine, opiates and amphetamines (Little et al. 1988; Holzman and Paneth 1994; Johnstone et al. 1996; English et al. 1997; Cnattingius 2004; Jaddoe et al. 2007). Other maternal factors associated with IUGR include extremes of reproductive age, and poor socioeconomic status (Naeye et al. 1973; Russell 1982; Wilcox et al. 1995; Ahluwalia et al. 2001; Smith et al. 2003). Severe maternal medical disorders may affect uterine artery blood flow; for example, vasculopathy associated with long-term diabetes (Haeri et al. 2008), chronic hypertension (Gilbert et al. 2007) and renal disease (Jones and Hayslett 1996; Fink et al. 1998). Maternal obesity increases the risk of developing these medical disorders and their complications

in pregnancy, including IUGR. Severe maternal anaemia (Levy et al. 2005), poorly controlled asthma (Bracken et al. 2003) or cyanotic heart disease may reduce maternal oxygen supply to the placenta (Drenthen et al. 2007). Certain maternal drug treatments such as beta-adrenoreceptor antagonists, phenytoin and long-term corticosteroids have been shown to have a negative effect on fetal growth (Montan 2004).

Factors affecting the transfer of substrates (IUGR of placental origin)

Poor placental function and resulting substrate deprivation are responsible for the majority of IUGR pregnancies. Placentae of IUGR pregnancies show reduced cytotrophoblast invasion and reduced surface area, increased thickness of the exchange barrier formed by the trophoblast and the fetal capillary endothelium, reduced villous density with fewer loops and coils, atheromatous change within the maternal spiral arteries, increased placental apoptosis and piling up of trophoblast due to shedding of apoptotic cells (Sheppard and Bonnar 1976; Giles et al. 1985; Jackson et al. 1995; Krebs et al. 1996; Smith et al. 1997; Kingdom et al. 2000). Normal placental development requires successful trophoblast invasion into the inner third of the myometrium and the entire length of maternal spiral arteries. The trophoblast cells destroy the muscular and elastic walls of these vessels, resulting in large flaccid uteroplacental vessels (Brosens et al. 1967). Conversion of high-resistance spiral arteries into low-resistance uteroplacental vessels is necessary to accommodate the massive increase in uterine blood flow observed in pregnancy to meet the metabolic demands of the fetoplacental unit.

To assess changes in volume blood flow within the placental circulation requires the measurement of vessel diameter, which is difficult for small vessels. However, changes in vascular resistance in the uteroplacental circulation can be assessed non-invasively using Doppler ultrasound waveform analysis of pulsatile flow in the umbilical artery (fetoplacental circulation) and uterine artery (maternoplacental circulation). The shape of the uterine or umbilical artery waveform showing high diastolic velocity with continuous diastolic flow indicates a high-flow, low-resistance uteroplacental circulation. The waveform can also be quantified by using the ratio of systolic to diastolic maximum velocity (S/D), the pulsatility index (PI; peak systolic flow minus end-diastolic flow divided by mean flow) or the resistance index (RI; peak systolic flow minus end-diastolic flow divided by peak systolic flow). The PI is the most widely studied Doppler index.

It has been shown that trophoblast invasion in early pregnancy is more extensive in pregnancies with low-resistance compared with high-resistance Doppler indices in the uterine artery (Prefumo et al. 2004). In non-pregnant women the high-resistance uteroplacental vasculature leads to a rapid rise and fall in velocity during systole, an early diastolic 'notch' in the waveform, and low end-diastolic flow velocities (Schulman et al. 1986). Spiral artery transformation results in a significant reduction in uterine artery resistance (decreased PI and RI) between 8 and 26 weeks of gestation, and a loss of the diastolic 'notch' between 20 and 26 weeks of gestation (Jauniaux et al. 1992; Thaler et al. 1992). Diastolic flow in the umbilical artery also increases as gestation increases in a normal pregnancy, producing a fall in the PI (Hendricks et al. 1989; Reed 1997).

Placentae from pre-eclamptic pregnancies share many histological features with the placentae of IUGR pregnancies, suggesting a common pathogenesis. In addition, both pre-eclamptic and IUGR pregnancies are associated with increased resistance or impedance

to uterine artery blood flow (Trudinger et al. 1985; Ducey et al. 1987). Pre-eclampsia is a pregnancy-specific systemic endothelial disorder which affects about 2% of pregnancies. Although the development of maternal hypertension in the second half of the pregnancy with the presence of significant proteinuria is diagnostic of pre-eclampsia, the aetiology is heterogeneous with variable clinical presentation (Sibai et al. 2005). Early-onset pre-eclampsia (before 34 weeks of gestation) is associated with a higher incidence of poor placental function, a more severe IUGR with a higher risk of maternal mortality and morbidity (Witlin et al. 2000). Conversely, late-onset pre-eclampsia is more prevalent but with minimal placental dysfunction.

A single umbilical artery (SUA) is associated with a 20-fold increased risk of cardiac anomalies and a threefold increased risk of renal anomalies. However, even in fetuses with isolated SUA there is a twofold increased risk of IUGR (Hua et al. 2010). Both acquired (e.g. antiphospholipid syndrome) and inherited thrombophilias predispose to IUGR, as they may increase the risk of thrombotic lesions within the placenta (Yasuda et al. 1995). It has been suggested that there is an increased frequency of the prothrombin mutation and the methyltetrahydrofolate reductase mutation in mothers of IUGR babies (Kupferminc et al. 1999). Tobacco smoking increases the risk of SGA and acts in a dose- and gestation-dependent manner to reduce birthweight, probably via adverse effects on placental blood flow (Thompson et al. 2001). A recent SCOPE study showed that the SGA rate in women who stopped smoking by 15 weeks of gestation was equivalent to that of non-smokers (McCowan et al. 2009).

Endocrine factors

Important regulators of fetal growth, differentiation and function are the insulin-like growth factors (IGF), including IGF-1 and 11, IGF-binding proteins (IGFBP) 1–6, IGF receptors 1 and 2 and IGFBP-specific proteases. IGF plays an important role in trophoblast invasion (Lawrence et al. 1999), and abnormalities in IGF signalling have been associated with IUGR (Irwin et al. 1999). A reduced fetal serum IGF-1 is associated with IUGR, while overexpression of IGF-11 is associated with fetal overgrowth, as observed in Beckwith-Wiedemann syndrome. In addition, low plasma IGFBP-1 in early pregnancy is associated with an increased risk of pre-eclampsia. Pregnancy-associated plasma protein A (PAPP-A) is a trophoblast-derived protease that cleaves IGFBP-4, thus increasing the bioavailability of IGF (Laviola et al. 2005). A low maternal serum PAPP-A in the first trimester of pregnancy is also associated with an increased risk for subsequent development of pre-eclampsia (Poon et al. 2008), and PAPP-A levels are significantly lower in women developing early-onset than late pre-eclampsia (Poon et al. 2010).

In addition, decreased levels of angiogenic proteins, such as vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), and increased levels of angiogenic inhibitor, such as fms-like tyrosin kinase 1 (sFlt-1), are associated with reduced trophoblast invasion (Savidou et al. 2006; Smith et al. 2007; Stepan et al. 2007). There is an inverse correlation between maternal PlGF and uterine artery PI (Schlombach et al. 2007). Elevated maternal sFlt-1 is associated with increased uterine artery PI, pre-eclampsia and IUGR; and higher sFlt-1 levels were observed in women with adverse pregnancy outcomes resulting in delivery before 34 weeks of gestation. An inverse correlation has been shown between birthweight and maternal corticotrophin-releasing hormone (CRH) levels at 33 weeks of gestation. An elevated CRH level is associated with a 3.6-fold increased risk of IUGR (Wadhwa et al. 2004). In addition, there is a relationship between birthweight and maternal neurokinin B and nitric oxide metabolite levels (D'Anna et al. 2004).

Physiological sequelae of IUGR

The majority of fetuses with IUGR will be substrate-deprived due to the abnormal transfer of oxygen and nutrients (glucose, amino acids, lipids) across the placenta. Insights into the fetal responses to such deprivation are important as they: (1) underpin the rationale for the techniques used to monitor fetal wellbeing; (2) often lead to improved short-term survival; and (3) can also cause some of the short- and long-term complications associated with IUGR.

Fetal heart rate

Acute fetal hypoxaemia is associated with well-described changes in fetal heart rate (FHR); these underpin the use of electronic fetal monitoring on the labour ward (Ch. 12). However, experiments in fetal sheep where the fetoplacental circulation was embolised every

day for 10 days leading to chronic hypoxaemia and a 50% reduction in umbilical flow did not change baseline FHR or lead to decelerations or changes in short-term variability (Gagnon et al. 1996). These suggest that changes in FHR patterns are likely to be a late occurrence in the sequence of haemodynamic change seen in the IUGR fetus (Fig. 10.1), and agree with studies from human fetuses with absent end-diastolic flow in the umbilical artery. Here, abnormal FHR patterns were only observed when the middle cerebral artery (MCA) began to lose its compensatory maximal dilation, i.e. the fetus was entering a preterminal phase (Weiner et al. 1994).

Regional blood flow

In contrast, changes in regional blood flow with maintained, chronic fetal hypoxaemia are well described in a number of animal species. In fetal sheep blood flow to the brain, heart and adrenal

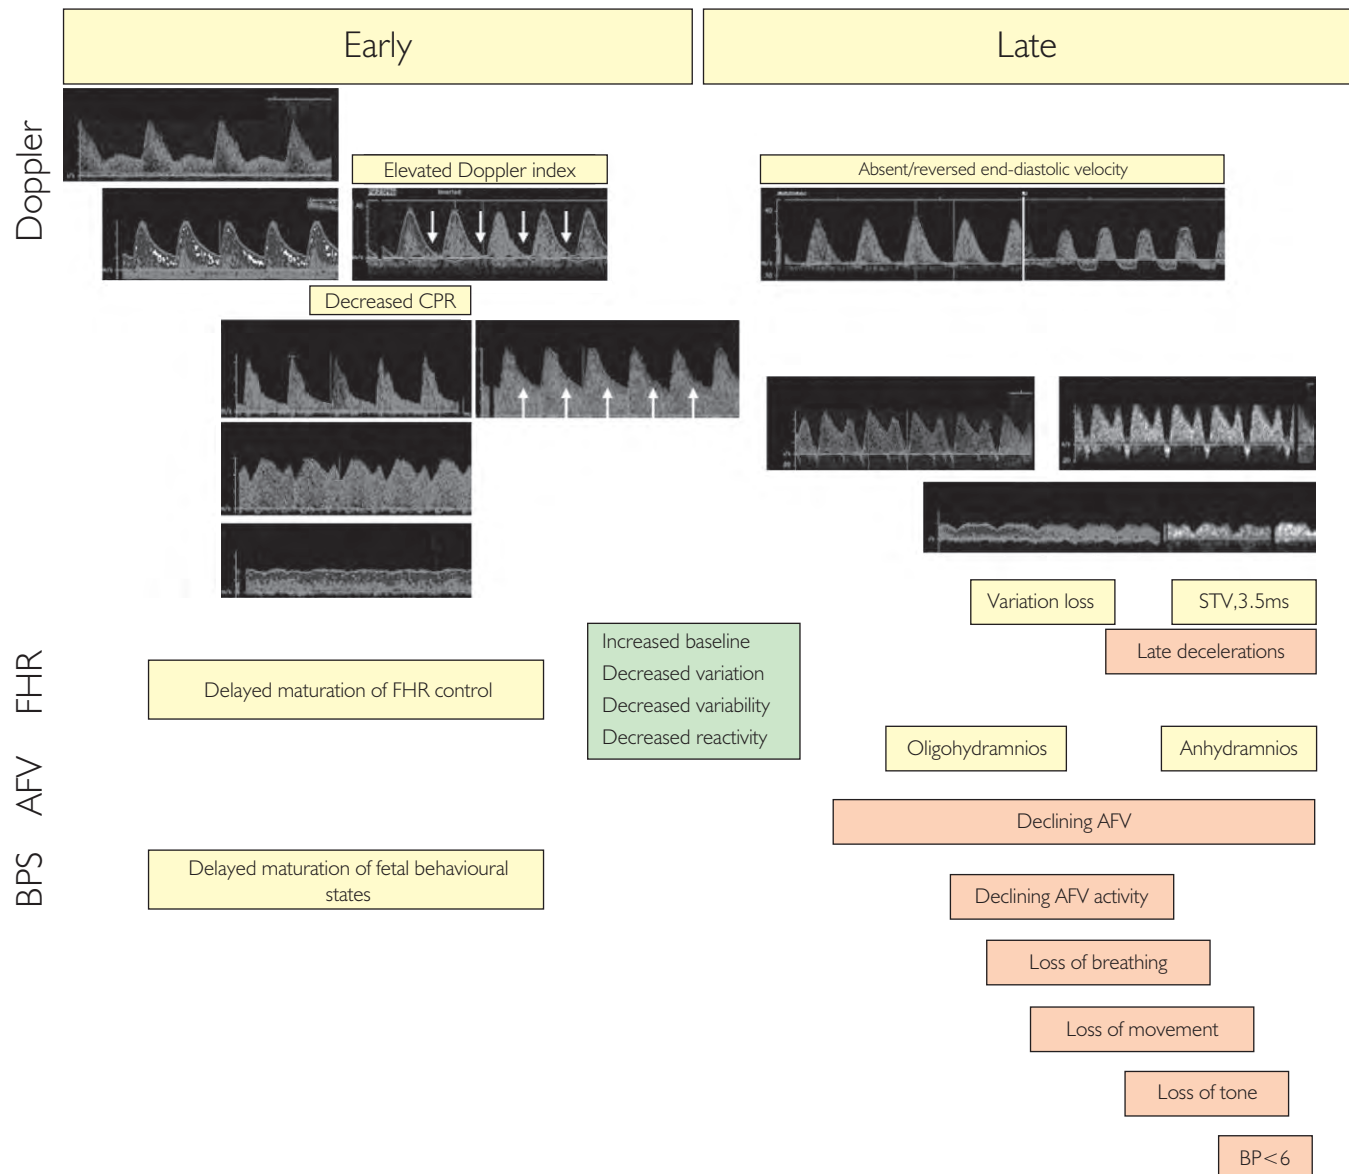

Fig. 10.1 Schematic representation of sequential changes in fetal physiological parameters observed in intrauterine growth restriction fetuses with worsening acid-base status. glands increases rapidly with the onset of acute hypoxaemia and remains high if hypoxaemia is maintained; this effect is observed from mid- to late gestation (Bocking et al. 1988; Matsuda et al. 1992; Richardson et al. 1996). The effect of the increased blood flow is to maintain substrate delivery that is critically important for the maintenance of growth and optimal function of these key organs. Doppler studies in fetuses with IUGR suggest that vascular resistance is increased in a variety of vessels, including the splanchnic, renal and pulmonary circulations, suggesting that the reductions in blood flow to the gut, kidneys and lungs that are observed during acute hypoxia in fetal sheep are maintained during sustained hypoxaemia (Vyas et al. 1989; Mari et al. 1995; Rizzo et al. 1996). Detection of substrate deficiency occurs both locally and at central chemoreceptors and is sensitive and rapid; detection of cerebral vasodilation is therefore an early finding in IUGR.

Abnormal cerebral blood flow is an extremely sensitive test for the prediction of IUGR, but it has poor specificity in the detection of adverse perinatal outcome (Chan et al. 1996). Whilst redistribution of cardiac output optimises short-term survival with chronic hypoxaemia, there is some evidence that it is responsible for some of the immediate postnatal complications observed in growth-restricted neonates. Kempley et al. (1991) described a reduction in flow velocity, which persisted until the end of the first week of life, in both superior mesenteric artery and the coeliac axis in growth-restricted compared with normally grown neonates of similar gestational age. The increased incidence of necrotising enterocolitis (NEC) observed in IUGR fetuses may be related to ischaemic damage occurring either in utero or following delivery (Hackett et al. 1987). Oligohydramnios, a common finding in IUGR pregnancies, is probably related to reduced renal perfusion and glomerular filtration. Again, chronic reduction in lung growth might underlie the excess incidence of chronic lung disease observed in infants with severe IUGR (Lal et al. 2003). Because of the correlation between the growth of an organ and its blood supply, organ size appears to be a sensitive indicator of redistribution of cardiac output; indeed, relative shortening of the femurs in the early second trimester has been reported as an early sign of incipient growth restriction, often preceding other evidence by several weeks (Todros et al. 2004).

In addition to the redistribution of cardiac output, chronic hypoxia can also influence the venous pattern of blood flow and return of blood to the heart. Approximately 25–50% of blood returning from the placenta via the umbilical vein is shunted via the ductus venosus (DV), which connects with the inferior vena cava near its entrance to the heart (Behrman et al. 1970; Edelstone and Rudolph 1979). This well-oxygenated blood is preferentially streamed through the foramen ovale into the left atrium and from there towards the cardiac and cerebral circulations (Kiserud 1999). In both human and other mammalian fetuses the amount of blood flowing through the DV increases during hypoxia (Behrman et al. 1970; Tchirikov et al. 1998). A direct consequence of increased DV shunting is that the proportion of umbilical vein flow that passes via the hepatic circulation is reduced; a fall in hepatic perfusion and decreased substrate supply can impair liver function and glycogen synthesis and storage (reflected in a decrease in growth velocity in the abdominal circumference). Not surprisingly, flow velocity is maintained in the DV even with severe IUGR (Kiserud et al. 1994), because the DV and left atrium are linked by a direct column of blood. Increases in left atrial filling pressure, due mainly to impaired ventricular contractility, but also increased afterload, will lead to reduced forward flow in the DV during atrial systole. Decreased or absent flow during atrial systole is a late finding in the haemodynamic response to hypoxia and, because it indicates cardiac

compromise, correlates strongly with poor perinatal outcome (Baschat et al. 2003).

The consequences of IUGR

The short-term consequences of IUGR include the increased risk of perinatal mortality, and perinatal morbidity, including birth asphyxia, meconium aspiration and the consequences of preterm birth. About half of IUGR survivors will have significant short- or long-term morbidity (Dobson et al. 1981). The extent and severity of morbidity depend on the cause and severity of IUGR and the neonatal consequence of fetal adaptation to chronic hypoxia, complications during labour and delivery, the gestational age at birth and immaturity of function, place of birth and the presence of chromosomal or structural anomalies. The commonest causes of death are prolonged hypoxia, birth asphyxia, prematurity and congenital anomalies. It is anticipated that a preterm IUGR baby will have more complications than a term IUGR baby and would require specialist neonatal care from birth. An IUGR fetus with chronic hypoxia is at increased risk of birth asphyxia at all gestational ages (McIntire et al. 1999). In the immediate neonatal period, birth asphyxia and metabolic acidosis may lead to multiorgan dysfunction, including hypoxic–ischaemic encephalopathy, seizures, intraventricular haemorrhage, respiratory distress due to surfactant deficiency, meconium aspiration or pulmonary haemorrhage, persistent pulmonary hypertension, hypotension due to myocardial dysfunction, transient tricuspid valve insufficiency, renal failure due to acute cortical necrosis, coagulopathy and elevated aminotransferase due to liver hypoxia, hypocalcaemia, and adrenal insufficiency due to haemorrhage (Kramer et al. 1990; Villar et al. 1990; Gilbert and Danielsen 2003).

The fetal redistribution of circulation to vital organs in response to hypoxaemia and substrate deprivation may lead to problems with neonatal adaptation to extrauterine life. For example, there is an increased risk of NEC due to bowel ischaemia. The risk of NEC is higher in IUGR babies with absent or reversed end-diastolic flow in the umbilical artery before birth (Dorling et al. 2005). Since the reduced splanchnic blood flow may persist in the first week of life, oral feeding should be introduced cautiously during this time. Other complications include hypoglycaemia due to limited glycogen stores; polycythaemia due to the increased synthesis of erythropoietin in chronic hypoxia and consequently hyperviscosity, renal vein thrombosis and hyperbilirubinaemia; respiratory distress syndrome; problems with thermoregulation due to limited adipose tissue stores and a relatively large body surface area; retinopathy of prematurity; and hyperglycaemia due to low insulin secretion in very preterm neonates.

Beyond the neonatal period, there is an increased risk of developing neurological abnormalities including cognitive delay and cerebral palsy, especially in babies born preterm (Wood et al. 2000; Yanney and Marlow 2004). Magnetic resonance imaging of the brain of IUGR infants has shown reduced volume of cerebral cortical grey matter (Tolsa et al. 2004). About 90% of babies with SGA will show catch-up growth by 6 months of age, but 10% will remain below the third percentile for height at 2–3 years of age and may benefit from growth hormone therapy (Saenger et al. 2007). However, animal models have shown that IUGR is associated with reduced leptin levels, a satiety factor which controls appetite and food intake (Geary et al. 1999). Although the level of leptin increased in the adult IUGR offspring, there is a decreased anorexic response to leptin, and this is especially demonstrated in IUGR offspring with rapid catch-up growth (Desai et al. 2007). It has been

suggested that altered control of appetite in the adult IUGR offspring leads to adult obesity. Besides obesity, there is a growing body of evidence to support the concept that there are fetal origins for adult diseases such as adult hypertension, high cholesterol levels, type 2 diabetes mellitus, abnormal coagulation factors, coronary heart disease, stroke, bronchitis, premature menopause in women and Down syndrome pregnancy (Barker and Osmond 1986; Barker et al. 1989a, b, 1992, 1993, 1997; Barker 1990; Phipps et al. 1993; Martyn et al. 1995; Cresswell et al. 1997; Shaheen 1997; Van Montfrans et al. 2001). One hypothesis is that the IUGR fetus is programmed to exhibit the 'thrifty phenotype' where the metabolism is permanently reset to adapt to poor nutritional conditions, such that the extrauterine exposure to western diet predisposes the offspring to obesity and metabolic syndrome as an adult.

Primary prevention of IUGR

Prepregnancy counselling and health education, as well as optimising any pre-existing medical conditions before pregnancy, are important. Prepregnancy folic acid supplementation to prevent neural tube defects should be advocated, as well as the importance of good nutrition, the avoidance of harmful substances such as smoking, alcohol, illicit drug abuse, and reduction of caffeine intake (Ouellette et al. 1977; Lumley et al. 2006). In addition, women should be informed that smoking cessation before the third trimester will reduce the risk of IUGR (Lieberman et al. 1994). In women who have a high risk of pre-eclampsia, low-dose aspirin reduces the risk of developing pre-eclampsia by 17% and reduces the risk of SGA by 10% (Duley et al. 2007).

Since maternal obesity increases the risk of hypertensive disorders in pregnancy, which in turn increases the risk of IUGR (Callaway et al. 2006), it may be beneficial to encourage weight loss before pregnancy, or to limit weight gain during pregnancy in obese women (Cedergren 2006). Women with eating disorders should also be counselled regarding the increased risk of IUGR pregnancies. It has been shown that a pregnant woman with a body mass index of less than 20 has a higher risk of an SGA fetus when the total gestational weight gain is less than 8 kg, in comparison with a weight gain of more than 16 kg (Cedergren 2007). However, the provision of social support for women of low socioeconomic status has not been shown to reduce the incidence of SGA, as poor diet is the probable mechanism by which socioeconomic status influences growth (Hodnett and Fredericks 2003).

In order to prevent congenital infection and IUGR, all women should be vaccinated against rubella before pregnancy. In malaria-endemic areas, the routine use of antimalarial drugs and insecticide-treated nets for women in their first two pregnancies has been shown to reduce the incidence of low-birthweight babies (WHO 2005; Garner and Gulmezoglu 2006). Antiretroviral treatment in women with HIV infection can reduce in utero maternal-to-child-transmission of HIV from 25% to 2%, and thus prevent IUGR due to congenital HIV infection (WHO 2006).

Antenatal screening and diagnosis

The antenatal diagnosis of IUGR relies on a number of observations, including: (1) current fetal size, taking into account the fetal growth potential such as ethnicity, fetal gender, maternal height and parity; (2) serial ultrasound measurements of fetal size to demonstrate reduced growth velocity, where the EFW decreases in its percentile value for gestational age; (3) indicator of fetal compromise,

where fetal Doppler demonstrates redistribution of fetal circulation in response to hypoxaemia, particularly a decreased impedance to MCA blood flow; and (4) indicator of poor uteroplacental function, where uterine artery Doppler (UAD) indicates a persistent high-resistance circulation at 24 or more weeks of gestation and/or umbilical artery Doppler waveform shows increased impedance to blood flow.

However, in an unselected obstetric population, the evidence does not support the use of routine fetal biometry after 24 weeks of gestation, routine umbilical artery Doppler ultrasound, routine UAD ultrasound or routine antenatal electronic fetal heart monitoring for the prediction of IUGR (Goffinet et al. 1997; Chien et al. 2000; Royal College of Obstetricians and Gynaecologists 2002). Each screening tool will have a higher positive predictive value if there is an increased risk of IUGR based on maternal history and clinical examination. Therefore, the principle of antenatal care is the identification of pregnancies at high risk of IUGR through history, examination, and biochemical and ultrasound screening.

Ultrasound assessment of gestational age and fetal size

A reliable estimate of gestational age is a prerequisite for the early detection of IUGR, interpretation of serum screening tests and planning for elective delivery. Gestational age is the strongest determinant of fetal size and perinatal outcome. The last menstrual period (LMP) should not be used alone to date a pregnancy. Even if LMP is recalled accurately, it is not a precise indicator of the conception date (Geirsson and Busby-Earle 1991; Savitz et al. 2002; Nakling et al. 2005). This is because the timing of ovulation varies cyclically, even in women with regular menstrual cycles. In addition, errors in recall are common, with a tendency to digit preference when recalling dates, and falsely identifying non-menstrual bleeding as a menstrual period (Gjessing et al. 1999; Nakling et al. 2005).

Dating methods using ultrasonographic assessment of fetal size before 20 weeks of gestation have been shown to reduce the percentage of pregnancies classified as 'postterm' by up to 74% when compared with dating based on LMP only. In the first trimester of pregnancy (up to 14 weeks), ultrasound measurement of the fetal crown-rump length (CRL) provides a relatively accurate estimate of gestational age, with a standard deviation of approximately 7 days (Hogberg 1997; Taipale and Hiilesmaa 2001). The CRL measurement becomes less reliable beyond 13 weeks because the fetus becomes increasingly flexed with advancing gestation.

In the second trimester, the most accurate estimate of gestational age is the head circumference (HC), while the most sensitive indicator of fetal size is the abdominal circumference (AC) (Chang et al. 1993; Chitty et al. 2007). The accuracy of dating using HC is improved with the addition of AC and femur length (FL) measurements, such that fetal biometry in the second trimester also provides an accurate estimate of gestational age within 7 days (Chervenak et al. 1998). In addition, the calculation of EFW is more accurate using all three biometric measures than any one measurement alone (Hadlock et al. 1985). Using the Hadlock formula, which combines HC, AC and FL, the EFW is within 15% of the actual fetal weight when the fetus weighs between 1500 and 3999 g (Benson and Doubilet 1991). Errors as high as 25% between the predicted and actual fetal weight occur when a fetus weighs below 1500 g, with the tendency to overestimate fetal weight; or when a fetus weighs above 4000 g, with the tendency to underestimate (Manning et al. 1981).

Most obstetric units use a combination of the LMP and dating based on ultrasound fetal biometry, only favouring the ultrasound dates if the discrepancy is greater than 7, 10 or 14 days depending on gestational age at first ultrasound scan. However, it is recommended that the use of CRL measurement between 10 and 13 weeks alone should be used to determine gestational age (National Institute for Health and Clinical Excellence 2008). For women who booked late for antenatal care, the use of ultrasound for dating is less reliable beyond 24 weeks, owing to the increased variation in fetal growth rate and imprecise measurements as a result of descent of the fetal head into the pelvis, shadowing from fetal bony parts and fetal crowding (Campbell et al. 1984). The transcerebellar diameter is a useful adjunct in determining gestational age in the second and third trimester because its measurement is independent of fetal head shape and there is a tendency for cerebellar growth to be preserved in IUGR (Chavez et al. 2004, 2007). However, if pregnancy dating is performed beyond 24 weeks, serial ultrasound scans should also be performed to confirm a normal growth velocity, instead of a one-off measurement of fetal size.

Identification of high-risk pregnancy

Once the best estimate of gestational age is determined, the principle of antenatal care is the recognition of pregnancies at high risk of IUGR through history, examination, and biochemical and ultrasound screening.

Maternal history

In addition to the risk factors mentioned in the aetiology section, women with recurrent bleeding should be regarded as high-risk. A previous IUGR pregnancy increases the risk of recurrent IUGR in subsequent pregnancies (Ananth et al. 2007).

Clinical examination

The traditional screening methods for fetal growth using abdominal palpation or measurement of symphysis–fundal height (SFH) have poor detection rates for IUGR. In a low-risk population, abdominal palpation has a sensitivity of only 21% and a specificity of 96% for detecting SGA fetuses (Bais et al. 2004). After 20 weeks of gestation, the SFH in centimetres from the upper edge of the pubic symphysis to the top of the uterine fundus approximates to the number of weeks of gestation. Differences in maternal build and subjectivity of this test have led to a considerable variation in the results of studies using SFH, with the largest study showing a sensitivity of only 27%, and a specificity of 88% for detecting SGA fetuses (Persson et al. 1986). The selection of women with SFH that is below expectation for ultrasound fetal biometry reduces the false-positive rate for detecting SGA when compared with a policy of scanning all women in the third trimester, but the sensitivity is not improved with this method (Harding 1995).

Maternal serum screening

The combined test is offered to all women in the first trimester for Down syndrome screening. This involves fetal nuchal translucency scan and maternal serum PAPP-A and human chorionic gonadotrophin (hCG) levels. Women who missed the first trimester screening have the option of serum screening in the second trimester, including alpha-fetoprotein, oestriol, hCG and inhibin A. Pregnancies identified as high-risk for Down syndrome due to significantly reduced PAPP-A levels should be monitored for

fetal growth, even when invasive testing showed normal fetal karyotype.

Other methods of screening which have not been adopted in clinical practice include using angiogenic markers such as PlGF or sFlt-1. These have sensitivities of 55–60% and specificities of 60–70% of predicting pre-eclampsia or IUGR (Stepan et al. 2007). In addition, sFlt-1 had a higher sensitivity of 80% and a specificity of 94% for predicting adverse outcome resulting in delivery before 34 weeks of gestation.

Ultrasound screening

Ultrasound screening for structural malformation is offered to all women between 20 and 22 weeks of gestation. In the absence of structural malformations, the markers associated with an increased risk of IUGR include bright or echogenic fetal bowel, single umbilical artery, isolated short femur (where the femur is below the fifth percentile for gestational age but the abdominal circumference measurements and the EFW are within the normal range) (Weisz et al. 2008). Beyond 24 weeks of gestation, there is no evidence that routine ultrasound scan to assess growth in a low-risk population improves perinatal outcome, and it has been suggested that this may increase the rate of caesarean section.

Screening for adverse outcome using UAD has produced variable results depending on gestational age, presence of risk factors and severity of outcome. In a study of high-risk multiparous women, abnormal UAD had a sensitivity of 80% and a positive predictive value of 70% for identifying women who subsequently developed pre-eclampsia, SGA below the fifth percentile, placental abruption, preterm birth and perinatal mortality (Harrington et al. 2004). In a recent systematic review and meta-analysis of 74 studies totalling 79 547 patients with pre-eclampsia and 61 studies of 41 141 IUGR pregnancies, it was reported that an abnormal UAD waveform had a higher predictive value for both pre-eclampsia and IUGR when performed in the second trimester (beyond 16 weeks of gestation) than in the first trimester (Cnossen et al. 2008). Screening with UAD was also more predictive of pre-eclampsia than IUGR, and increased PI with diastolic notching was the best predictor of pre-eclampsia (positive likelihood ratio of 21 for high-risk patients and 7.5 for low-risk patients). Increased PI and diastolic notching were the best predictors of IUGR in low-risk patients (positive likelihood ratio 9.1). For severe IUGR, the predictive value was higher (positive likelihood ratio 14.6).

Identifying IUGR using ultrasound fetal biometry

Ultrasound of fetal size alone has a low predictive ability and high false-positive rate for detecting IUGR. The fetal AC indicates the nutritional state of the fetus, as this is a measure of subcutaneous, intra-abdominal and extraperitoneal fat and liver size. An AC below the 10th centile was found to predict SGA with an odds ratio of 13.5 in a low-risk population and 18.4 in a high-risk population (Chang et al. 1992). A more recent study has shown that the accuracy of predicting SGA was similar when either the AC or the EFW alone was below the 10th centile. In addition, the likelihood of SGA was found to be greater when both the AC and the EFW were below the 10th centile (Chauhan et al. 2006). Although EFW calculations do not aid in the diagnosis of IUGR, they are helpful in planning delivery and neonatal care. Serial measurements of fetal biometry every 2–4 weeks should be used to identify any deviation of growth across the centiles.

Ultrasound assessment of liquor volume

Liquor volume is assessed by measuring the maximum pool depth, or, more accurately, by adding the pool depth in each quadrant of the uterus to produce the amniotic fluid index. Although oligohydramnios is associated with more severe IUGR, the predictive value of these measurements is limited, so they are used as an adjunct to other elements of the fetal assessment.

Management of IUGR and timing of delivery

Currently, there is no therapy for IUGR and the most effective intervention is timely delivery of the baby. Other interventions to be considered include: (1) reduction of maternal risk factors, e.g. smoking reduction; (2) maternal administration of corticosteroids if preterm birth is anticipated; and (3) delivery in a unit with appropriate neonatal intensive care facilities (Roberts and Dalziel 2006). The perinatal outcome of an IUGR pregnancy, and thus its management, depends on the aetiology, gestational age, severity of IUGR and severity of maternal disease.

Investigation of IUGR aetiology

Ultrasound scan should be performed to exclude structural malformations. The presence of sonographic soft markers in a structurally normal fetus may indicate the possibility of aneuploidy. Amniocentesis or chorionic villus sampling should be offered to identify chromosomal abnormality. Isolated karyotypic abnormalities within the placenta are also associated with IUGR. The diagnosis of maternal infection is important and maternal serology tests for toxoplasmosis, cytomegalovirus and rubella should be performed. If maternal serology is positive, amniocentesis should be considered to confirm fetal infection.

Timing of delivery

In fetuses with no chromosomal or structural abnormality, the timing and mode of delivery should take into account the risk of morbidity due to iatrogenic preterm delivery (such as respiratory distress syndrome and brain injury), the risk of continuing intra-uterine hypoxia and stillbirth, and the severity of maternal disease. Thus, antenatal fetal and maternal surveillance should be performed diligently. Fetal surveillance consists of serial ultrasound assessment of growth (usually every second week), liquor volume, Doppler assessment of the fetal circulation and maternal uterine artery and FHR monitoring. Since pre-eclampsia occurs in up to 40% of cases of IUGR, maternal surveillance for raised blood pressure, proteinuria and biochemical markers is also important.

In a large prospective study of 604 infants born before 34 weeks because of severe IUGR, gestational age was the most important determinant of overall survival before 27 weeks and intact survival before 29 weeks; if the fetus was delivered after these gestations and weighed more than 600 g then DV Doppler was the only predictor of adverse outcome (Baschat et al. 2007). Besides gestational age, the finding of an abnormal fetal umbilical artery Doppler in high-risk pregnancies is more predictive of adverse outcome than a biophysical profile or fetal heart trace (Gonzalez et al. 2007).

Increased resistance (high PI or RI) in the umbilical artery in high-risk pregnancies indicates IUGR of placental origin, and is associated with increased risk of antenatal admissions, inductions of labour, operative delivery, increased admission to neonatal units and increased perinatal mortality (Hackett et al. 1987;

Gudmundsson and Marsal 1988; Wilson et al. 1992). Meta-analyses indicate that the use of Doppler ultrasound to guide clinical decision-making is likely to improve outcomes in pregnancies with suspected IUGR and pre-eclampsia (Alfirevic and Neilson 1995; Neilson and Alfirevic 2001). When Doppler ultrasound was used to guide management, perinatal mortality was reduced by 38%.

The Growth Restriction Intervention Trial (The GRIT Study Group 2003) recruited pregnancies between 24 and 36 weeks of gestation with abnormal umbilical artery Doppler waveform when the clinicians were uncertain about the timing of delivery. These pregnancies were randomised to either immediate delivery after completion of antenatal corticosteroids or deferred delivery until there was abnormal FHR or favourable gestational age. It was found that the perinatal mortality rates were the same in both groups. Clinicians were prepared to delay delivery by about 4 days, resulting in a fivefold higher stillbirth rate. However, in the immediate-delivery group, there was a similar rate of early neonatal deaths (The GRIT Study Group 2003). The neurological outcomes at 2 years also showed no statistically significant difference in both groups in babies born after 31 weeks of gestation. However, there was a trend towards more disability in the immediate-delivery group for babies delivered before 30 weeks of gestation (Thornton et al. 2004).

Since the GRIT trial, more recent studies have investigated in more depth the phases of fetal Doppler abnormality. Doppler ultrasound of MCA showing increased diastolic velocity (reduced PI) identifies IUGR fetuses with redistribution of blood flow to the brain. These changes in SGA fetuses have been associated with the development of abnormal FHR patterns and increased admission to the neonatal unit (Mari and Deter 1992). Changes in the MCA occur relatively early in the process of hypoxia, and although it is used to confirm the diagnosis of IUGR, it is not useful in deciding the timing of delivery. However, normalisation of the PI values suggests a deteriorating fetus.

Significant predictors of adverse perinatal outcome are absent/reversed umbilical artery flow and absent/reversed α -wave in the DV Doppler waveform. Since the α -wave corresponds to end-diastolic atrial contraction, these changes reflect myocardial dysfunction and are late signs of fetal hypoxia and indicate imminent heart failure; such changes in DV flow are an indication for delivery, even at gestations less than 29 weeks (Fig. 10.1). A very late sign of fetal hypoxia which follows absent/reversed DV α -wave is the occurrence of pulsations in the umbilical vein and/or reduced short-term variability of FHR.

In IUGR fetuses at 30–34 weeks of gestation (where there is a good prospect of intact survival) the presence of absent/reversed end-diastolic flow in the umbilical artery is an indication for immediate delivery. Beyond 34 weeks of gestation, fetuses with IUGR typically have normal umbilical artery Dopplers (Chang et al. 1994), but are still at risk of poor outcome (Hershkovitz et al. 2000). Even if umbilical artery Doppler is normal, delivery should be considered if there is a decrease in growth velocity, oligohydramnios, abnormal cardiotocograph and/or evidence of cardiac redistribution (low MCA PI).

Fetal therapy for IUGR

There is insufficient evidence to support maternal bed rest, maternal oxygen administration or nutritional supplementation including routine zinc, magnesium, iron, folate or vitamin D supplementation (Crowther et al. 1990; Mahomed 2005a, b, c; Mahomed and Gulmezoglu 2005; Makrides and Crowther 2005; Say et al. 2005a, b, c). Calcium supplementation of 1 g/day during pregnancy has been shown to reduce the risk of hypertension in pregnancy and

pre-eclampsia but does not appear to reduce SGA, low birthweight or admission to neonatal intensive care unit (Hofmeyr et al. 2010). In addition, antihypertensive treatment for maternal hypertension has no beneficial effect on fetal growth. The use of vasodilating agents such as L-arginine, a nitric oxide donor, has been shown to improve uterine artery blood flow; however a randomised clinical trial is needed to evaluate its use as therapy for IUGR (Sieroszewski et al. 2004). A recent study showing that sildenafil increased mortality in growth-restricted fetal sheep highlights the challenge of avoiding systemic vasodilation and uterine hypoperfusion (Miller et al. 2009). Vector-mediated delivery of VEGF to the uterine arteries has been shown to increase uterine blood flow over a period of about 5 weeks and may be a potential candidate (David et al. 2008).

Mode of delivery

While the mode of delivery for IUGR pregnancies less than 35 weeks is more likely to be caesarean section following the administration of steroids, the optimal mode of delivery at later gestations is unclear. Even at term IUGR pregnancies are more likely to be delivered by caesarean section because of fetal distress and are more likely to have low Apgar scores, hypoglycaemia, respiratory distress and be admitted to a neonatal unit than fetuses with normal growth

velocities (Owen et al. 1997; Minior and Divon 1998). The severity of fetal hypoxia, parity and cervical assessment should be considered in deciding between induction of labour and caesarean section. Continuous electronic monitoring of the FHR pattern during labour is indicated because normal uterine contractions can lead to deterioration of fetal hypoxia. A pathological cardiotocograph can be investigated using fetal blood sampling or, if this is not possible, delivery by caesarean section.

Postnatal

Histological examination of the placenta is indicated following delivery of an IUGR fetus to confirm whether placental lesions were a contributory factor. Screening the baby for infection or congenital abnormality may be indicated. Babies with severe IUGR, especially when born preterm, should be routinely followed up to detect abnormal neurological development. Postnatal counselling of the mother is important since IUGR with absent or reversed EDF in the umbilical arteries has a recurrence risk of approximately 20%. In addition to IUGR recurrence, there is an increased risk of developing pre-eclampsia or placental abruption in subsequent pregnancies (Ananth et al. 2007). Consideration should be given to thrombophilia screening.

Good maternal health is necessary for the best pregnancy outcome. Women with chronic diseases, or those who become unwell during pregnancy, are often unable to make the optimal adaptations to pregnancy and therefore the best pregnancy outcome is compromised.

In this chapter are discussed medical conditions and illnesses which may be acquired during pregnancy, as well as chronic medical conditions and the way they may affect the health of mother and fetus.

Of most relevance to a neonatologist is the way maternal illness affects fetal development and the impact on neonatal health.

Women with chronic medical conditions should receive pre-pregnancy advice before embarking on pregnancy to ensure they are on safe and effective treatments and aware of the implications their condition may have on pregnancy.

The first part of this chapter will focus on serious conditions that can lead to the most unwanted outcome, maternal and perinatal death. Thereafter the focus will be on the most prevalent illnesses.

In each section are discussed the pathophysiology of the disease, its prevalence and incidence, the clinical presentation, appropriate

diagnostic tools, best management and outcomes. Where appropriate the impact on breastfeeding will also be discussed.

Thromboembolic disease

Venous thromboembolic events are a leading cause of maternal morbidity and mortality in the developed countries. This is in contrast to the developing world in which haemorrhage and complications from hypertensive disorders are the leading causes of maternal death. Fatal pulmonary embolism, although a rare complication of pregnancy, continues to be the leading cause of pregnancy-related mortality in western Europe and the USA as other causes of maternal mortality (haemorrhage, sepsis) have declined. More obesity in pregnancy, as well as higher caesarean delivery rates, over the past several decades has had an impact on this increased risk of complications for venous thromboembolism.

During pregnancy, the risk for venous thromboembolism is increased sixfold over the non-pregnant state and increases to 20-fold in the immediate puerperium.

Pathogenesis of thromboembolism in pregnancy

Pregnancy evokes a physiologically hypercoagulable state that is protective against haemorrhage at the time of delivery and placental separation. The hypercoagulable state of pregnancy is provoked by thrombin-mediated fibrin generation. The procoagulant changes of pregnancy include an increase in plasma concentration of coagulation factors and fibrinolysis inhibitors, reduced venous flow and increased venous dilatation. Physiological increases in all coagulation factors occur during pregnancy, with the exception of factors XI and XIII, which are frequently decreased. In addition, free protein S levels fall and acquired resistance to activated protein C develops during pregnancy. Risk for thromboembolism is further increased by compression of the inferior vena cava and iliac veins by the gravid uterus, promoting stasis. By 25–29 weeks' gestation, venous flow velocity is reduced by approximately 50% in the legs and does not return to normal non-pregnancy flow velocity until around 6 weeks postpartum. During pregnancy, local damage to pelvic veins may occur during vaginal and especially caesarean delivery and this provides an increased risk for thrombosis. When these physiological coagulation changes combine with genetic predisposition conditions such as thrombophilias, socioenvironmental factors and other medical factors (obesity, inactivity and caesarean section), the risk for thromboembolism is increased.

Most deep venous thrombosis (DVT) occurs in the antepartum period, equally distributed across all trimesters, whereas most pulmonary embolism occurs in the postpartum period.

Thromboembolism in inherited and acquired anticoagulation deficiencies

Thrombophilias are disorders of homeostasis that predispose to thrombotic events. The prevalence of inherited thrombophilias depends on the population and/or ethnicity. Approximately 15% of the western population is affected by a thrombophilia. Approximately 50% of cases of venous thromboembolism in pregnancy are associated with inherited or acquired thrombophilias. The absolute risk of venous thromboembolism for pregnant women with antithrombin III deficiency is reported to be as high as 40–68% (Dargaud et al. 2009; Brown and Hiatt 2010). Protein C, in its active form, is responsible for inactivation of factors V and VIII and

activation of fibrinolysis. Protein S is a vitamin K-dependent, naturally occurring inhibitor of haemostasis that is synthesised and released from the endothelium and shows autosomal dominant inheritance. It is a cofactor for protein C in the neutralisation of activated factor V and in fibrinolysis. The incidence of thromboembolism has been reported to be 2.5% per year for protein C-deficient individuals, and 3.5% per year for those with protein S deficiency (Brown and Hiett 2010). Protein C deficiency is also autosomal dominant, and the heterozygous trait results in plasma protein C levels of 55–65% of normal. During pregnancy, an incidence of DVT up to 25% has been reported for heterozygote protein C-deficient individuals. The risk for stillbirth is also increased in women with these protein deficiencies (Nelson and Greer 2006). Activated protein C resistance results from a point mutation in the factor V gene (the factor V Leiden mutation; FVL) and is the most frequent aetiology for thrombosis. The gene mutation is inherited as an autosomal dominant trait and is particularly prevalent in the white population. Heterozygosity for the FVL gene defect confers a five- to 10-fold increased risk for thrombosis.

Acquired thrombophilias include antiphospholipid antibodies and lupus anticoagulant. These conditions are typically diagnosed in women with recurrent pregnancy loss rather than thromboembolism. However, both disorders should be considered as risk factors for thromboembolism during pregnancy, and they may also increase the risk of thromboembolic disease in the fetus. For antiphospholipid antibody syndrome, the absolute risk for thrombosis has been reported to be as high as 30% (Nelson and Greer 2006).

Clinical presentation and diagnosis of thromboembolic disease

During pregnancy, venous thromboembolism may present with symptoms of DVT, or pulmonary embolism. The most common symptoms of DVT are pain, tenderness and swelling of the lower extremity. In pregnancy, 85% of DVT cases present in the left leg. This is due to the abrupt right-angle drainage of the left iliac vein that leads to more venous stasis in the left leg.

Clinical signs of a suspected DVT include heat, redness and swelling. The signs and symptoms result from obstructed venous return and/or in combination with vascular inflammation. The risk of pulmonary embolism is greater with femoral or iliac thrombosis and can occur without obvious swelling. Symptoms of pulmonary embolism include dyspnoea, pleuritic chest pain, cough and haemoptysis. Clinical signs include tachycardia, tachypnoea, crepitations, fever, pleuritic rub, cyanosis and the development of an accentuated second heart sound and gallop rhythm. Massive pulmonary embolism, defined as obstruction of more than 50% of the pulmonary circulation, may present with syncope, representing cardiovascular collapse, and recognised with hypotension.

Diagnostic evaluation test for thromboembolism

Doppler flow studies with compression sonography are the primary non-invasive tests used in the diagnosis of DVT. Compression ultrasonography has a sensitivity of 97% and a specificity of 94% for the diagnosis of symptomatic, proximal DVT in the general population. Doppler combined with real-time ultrasound and colour flow have become the diagnostic studies of choice in cases of suspected proximal vein thrombosis (Kearon et al. 1998). Imaging provides additional information about venous compressibility.

Magnetic resonance imaging (MRI) has a sensitivity for thrombi above the knee of nearly 100% and has a place in the evaluation of the patient suspected of having a pelvic thrombus with a negative Doppler/ultrasound examination. A chest X-ray to rule out other diagnoses is a first step in investigating the breathless pregnant patient. Computed tomography (CT) scanning, unlike ultrasonography and MRI, is associated with fetal as well as maternal radiation exposure.

D-dimer is a specific degradation product of cross-linked fibrin. Levels of D-dimer are increased in the presence of thrombi, but also increase with the progression of normal pregnancy and are therefore of little positive diagnostic value. Guidelines for the evaluation of pulmonary embolism in pregnancy attempt to balance diagnostic efficacy, decreasing maternal morbidity and mortality and minimisation of fetal exposure to ionising radiation. The most commonly used non-invasive study is the ventilation–perfusion scan (V/Q scan). Ventilation–perfusion lung scanning delivers a higher fetal dose of radiation (100–370 μ Gy) than does CT pulmonary angiography (PA) (3–131 μ Gy). Perfusion scanning alone in women with a normal chest X-ray reduces radiation exposure (Groves et al. 2006). Although helical CT gives good diagnostic sensitivity for pulmonary embolism, there are concerns about the future risk of maternal breast cancer following helical CT to the chest. Pulmonary embolism is however a life-threatening condition and pregnancy must not interfere with the most appropriate investigations when a pulmonary embolism is suspected.

Management of thromboembolism during pregnancy

Anticoagulation

Anticoagulation is the treatment of established DVT or pulmonary embolism occurring during pregnancy and the puerperium, and for prophylaxis against venous thromboembolism in women with a history of earlier thromboembolic episodes. Anticoagulation is also indicated for those women considered to be at risk because of the presence of a thrombophilic state. Low-molecular-weight heparin (LMWH) is the anticoagulant of choice for treatment of thromboembolism during pregnancy, and management requires an individualised, well-planned approach. Heparin does not cross the placenta and is not excreted into breast milk, giving the advantage over warfarin, which crosses the placenta and poses teratogenic fetal risk with exposure in the first trimester. LMWH preparations have more uniform activity, predictable dose–response, dose-independent mechanisms of clearance and longer plasma half-life than unfractionated heparin. An additional advantage of LMWH is that laboratory monitoring or dose adjustment is only required for those with high-risk thrombotic conditions such as metal heart valves or newly started on therapeutic LMWH.

Therapy for acute deep vein thrombosis–thrombophlebitis

Anticoagulation during pregnancy must be tailored to meet the needs of the women, especially peripartum. The current management approach for acute DVT during pregnancy is with twice-daily weight-based dosing of LMWH. However, in most pregnant women except those who are very overweight or underweight or those with impaired renal function, dose adjustments are not necessary.

Anticoagulation for labour and delivery

Anticoagulated patients are at risk of bleeding at the time of delivery. If a therapeutically anticoagulated patient needs an emergency

caesarean section, the preferred method of anaesthesia is a general anaesthetic.

During the postpartum period, anticoagulation can usually be resumed within 6 hours of delivery, but discussion with the anaesthetist is necessary regarding timing of removal of neuraxial anaesthesia.

In the postpartum period, anticoagulation with warfarin is an alternative to heparinisation. A therapeutic warfarin range is considered to be at a target international normalised ratio (INR) of 2.0–3.0 for oral anticoagulation in a patient with a first-time DVT. Warfarin is continued at a therapeutic dose for 6 months after a thromboembolic event, or until 6 weeks postpartum, whichever is the longer. No significant levels of warfarin appear in breast milk; therefore, women can breastfeed on warfarin. Warfarin is associated with a higher risk for bleeding complications than heparin, and requires close monitoring of the INR.

Postthrombotic syndrome occurs in up to 60% of patients after a DVT. Wearing a compression stocking on the affected leg after the acute event reduces the risk of this complication (McCull et al. 2000).

Therapy for pulmonary embolus

Acute treatment for pulmonary embolism during pregnancy includes prompt therapeutic anticoagulation with LMWH. Care coordination and management strategies are dictated by the critical nature of the woman's illness and her haemodynamic status.

Inferior vena cava interruption

Inferior vena cava interruption with filters to prevent recurrent thromboembolism is very rarely indicated. Difficulties retrieving filters have led to significant morbidity and therefore their insertion should be reserved for extraordinary situations when anticoagulation is required but not possible or is ineffective.

Thrombolytic therapy

Thrombolytics, such as streptokinase, urokinase and tissue plasminogen activator, have been used in the treatment of major pulmonary embolism during pregnancy. When there is haemodynamic collapse due to pulmonary embolus, the life-saving potential of thrombolytics generally exceeds the potential complications of haemorrhage (Leonhardt et al. 2006).

Management of women with a history of prior thromboembolism

Women with a history of DVT or pulmonary embolism during a prior pregnancy or while on oral contraceptives are at increased risk for recurrent thrombosis during subsequent pregnancies. Fifteen to 25% of thromboembolic events in pregnancy are recurrent events (James et al. 2007). The risk of recurrent thromboembolism in women with a prior pregnancy-related event has been reported to be 4–12%.

The usual treatment regimen for women with a prior DVT includes thromboprophylaxis with LMWH throughout pregnancy until 6 weeks postpartum. Thromboprophylaxis should be considered for those with a history of unprovoked thrombosis, morbidly obese pregnant women (body mass index >40) and those confined to bed for prolonged periods (e.g. premature rupture of membranes, placenta praevia). The use of pneumatic compression devices for the prevention of pregnancy-related thrombosis has not been well studied and the risks are primarily extrapolated from

perioperative data (ACOG Practice Bulletin 2007). Pulmonary embolism after caesarean delivery is much higher than after vaginal delivery by a factor of 2.5–20 (ACOG Practice Bulletin 2007). The duration of thromboprophylaxis after caesarean section for this high-risk group has not been studied. As the risk of peripartum DVT is highest during the first week or so postpartum, it is not unreasonable to continue mechanical means with a compression stocking or boot, or with low-dose LMWH for the first week after delivery.

Hypertension

Women can become pregnant with hypertension (chronic hypertension: 2–4% of pregnancies) or develop hypertension during pregnancy (gestational hypertension: 4%), or develop hypertension in association with proteinuria (pre-eclampsia: 4% of first-time pregnancies). Approximately 20% of women with pre-existing hypertension go on to develop pre-eclampsia. Hypertension during pregnancy is defined as a diastolic blood pressure of 90 mmHg or greater on two occasions more than 4 hours apart or a single diastolic blood pressure above 110 mmHg (Davey and MacGillivray 1988).

In normal pregnancy there is an increase in heart rate and cardiac output with a fall in total peripheral resistance. Cardiac output rises until the 24th week of pregnancy, by which time it has increased by approximately 45%. The rise in cardiac output does not keep pace with the fall in systemic vascular resistance and maternal blood pressure therefore tends to fall during the first and second trimester until about the 20th week, when it reaches its nadir. From this time total systemic vascular resistance begins to rise and so maternal blood pressure also rises gradually.

Clinical presentation

Chronic hypertension

Women with essential hypertension tend to be older, parous and likely to have a family history of hypertension. In pregnancies where pre-eclampsia does not develop, the risk of a poor outcome (intra-uterine growth restriction, preterm delivery, maternal renal and vascular problems) is directly proportional to the degree of hypertension and the number of antihypertensives that need to be used to control it. Most chronic hypertension is mild or moderate (<160/110 mmHg), and a good outcome can be expected unless pre-eclampsia develops. Antihypertensive medication can sometimes be discontinued in the first and second trimester because of the fall in blood pressure secondary to the physiological changes of pregnancy. The recent UK National Institute for Health and Clinical Excellence (NICE) guideline (2010) on the management of hypertension in pregnancy suggested that women with chronic hypertension should have a target blood pressure between 130/80 and 150/100 mmHg. This pragmatic recommendation protects the mother from cardiovascular end-organ damage while preventing reduced uteroplacental perfusion pressure that may lead to reduced fetal growth. There is no robust evidence to recommend beta-blockers, calcium channel blockers, methyldopa or any other antihypertensive over another. To some extent the choice is guided by clinician familiarity and maternal tolerance.

Pre-eclampsia

Pre-eclampsia is a multisystem disorder unique to humans and exclusively associated with pregnancy (Williams and de Swiet

1997). It is defined as a syndrome developing after 20 weeks of gestation, characterised by hypertension (a diastolic pressure of at least 90 mmHg on two consecutive occasions at least 4 hours apart) and proteinuria (>300 mg/24 hours). Across the world pre-eclampsia and eclampsia probably account for up to 50 000 maternal deaths per annum, the vast majority in the developing nations.

Pre-eclampsia develops in women predisposed to cardiovascular disease and who also have poor development of their placenta. The poorly perfused placenta appears to be the source of factors that lead to maternal vascular injury. This leads to a microangiopathy, which results in hypertension, multiorgan dysfunction and, on occasion, a consumptive coagulopathy (Williams and de Swiet 1997).

At present, there is uncertainty about the most effective prophylaxis against pre-eclampsia. Little can be done effectively to prevent pre-eclampsia. A meta-analysis of trials that tested the efficacy of low-dose aspirin (LDA) to prevent pre-eclampsia revealed a 15–20% decrease in incidence in those who received aspirin prophylaxis (Duley et al. 2001). Another Cochrane publication showed that calcium supplementation approximately halves the risk of pre-eclampsia (Hofmeyr et al. 2010). There is no additional benefit from magnesium, garlic, fish oil, antioxidant vitamins or folic acid.

Once pre-eclampsia has developed, it will progress at a variable rate until the fetus and placenta have been delivered. If a woman presents at term (>37 weeks), labour should be induced to prevent serious deterioration in the maternal and/or fetal condition. At earlier gestations, antenatal management aims to be conservative in order to prolong pregnancy and improve fetal maturity while attempting to avoid the development of severe maternal complications or fetal compromise.

Maternal investigations to assess the severity of pre-eclampsia include measures of renal and liver function and a platelet count. The assessment of fetal well-being should involve growth scans, assessment of liquor volume and umbilical artery Doppler velocimetry. Some women with pre-eclampsia have no evidence of fetal compromise while others have minimal maternal symptoms or signs but significant fetal compromise. Although control of blood pressure alone will do little or nothing to prevent disease progression, there is an increased risk of stroke, cardiac failure and abortion when hypertension exceeds 170/110 mmHg. By preventing significant rises in blood pressure, antihypertensives may help to allow a clinically useful period of fetal development and thus improve neonatal outcome.

A variety of antihypertensive agents are available; all act by different mechanisms. The new NICE (2010) guideline suggests the use of labetalol or nifedipine slow-release as first-line treatments (Visintin et al. 2010). When beta-blockers are given in high dose and throughout pregnancy for the treatment of chronic hypertension, they can be associated with intrauterine growth restriction (Rubin et al. 1983). The judicious use of beta-blockers in doses more usually prescribed since 2000 has not had the same association with fetal growth restriction. Angiotensin-converting enzyme (ACE) inhibitors should not be used in pregnancy as they are teratogenic (Cooper et al. 2006). ACE inhibitors do not appear to be secreted in breast milk in a clinically significant quantity and therefore they have a role in the management of postpartum hypertension.

Intravenous hydralazine or labetalol is the mainstay for the acute control of severe hypertension prior to delivery or in the immediate postpartum period. Acute hypotension must be avoided as uteroplacental blood flow can be compromised, leading to fetal compromise. Labetalol is a risk factor for neonatal hypoglycaemia and babies should be monitored.

HELLP syndrome

In 1982, Weinstein first used the term HELLP (haemolysis, elevated liver enzymes and low platelet count) syndrome to describe a particularly severe and rapidly progressive form of pre-eclampsia. Elevated liver enzymes and low platelets are common features of pre-eclampsia, but haemolysis is unusual. The importance of recognising haemolysis rests largely on the need to place women affected by HELLP at high risk of maternal and fetal mortality.

Eclampsia

Eclampsia is the development of seizures in association with pre-eclampsia. In the UK, eclampsia occurs uncommonly, affecting 5/10 000 pregnancies. While the term 'pre-eclampsia' suggests there is a progressive deterioration in the maternal condition to the point of eclampsia, almost 40% of eclamptic seizures occur before either hypertension or proteinuria is documented. About 40% of cases of eclampsia occur antepartum, 15% intrapartum and 45% postpartum, usually within the first 24 hours. The pathophysiology of the seizures is likely to be multifactorial; cerebral vasospasm causing both ischaemia and overperfusion have been observed, leading to disruption of the blood–brain barrier and cerebral oedema. Rarely, cortical blindness can occur.

There is clear evidence that magnesium sulphate is the drug of choice to prevent recurrent eclampsia in a woman who already has had an eclamptic seizure (Duley et al. 2003). The Magpie trial (2007) demonstrated that the use of magnesium sulphate in women with pre-eclampsia halved the incidence of eclampsia. At the dosage given in the trial there appeared to be no short-term serious harmful effects on either the mother or the baby. The recommendation is to use magnesium sulphate in women with severe pre-eclampsia and in those who have had an eclamptic seizure.

Heart disease

Owing to the major physiological changes to the heart in pregnancy, symptoms and signs of healthy pregnancy are often mistaken for pathology. The commonest reason for cardiological referral during pregnancy is the detection of a murmur that proves to be an innocent flow murmur in 90% of cases, due to the 50% increase in cardiac output. The other common presentation is with palpitations. The majority are due to benign arrhythmias such as ventricular and atrial unifocal ectopics that do not require treatment. Serious dysrhythmias are rare. The principles of treatment are no different from in non-pregnant patients, with the exception of some dysrhythmic agents that may be restricted because of insufficient safety data. Adenosine and direct current cardioversion can be used safely during pregnancy and are well tolerated by the fetus. Beta-blockers are first-line treatment to prevent supraventricular arrhythmias (Trappe 2003).

Heart disease in pregnancy is the leading cause of maternal mortality in the UK (Confidential Enquiry into Maternal Death in the UK 2002). In developed countries, the incidence of heart disease in pregnancy has declined over the last 50 years owing to the dramatic reduction in the incidence of rheumatic fever that followed the introduction of penicillin (Lupton et al. 2002). In contrast, congenital heart disease in pregnancy is increasingly common because of the advances in paediatric cardiac surgery and medical therapy which have taken place over the last 30 years, which mean that more affected women are surviving into the reproductive age. The risk of a child inheriting polygenic cardiac disease is varied according to the parent's condition, being 3% in conditions such as tetralogy of

Fallot but as high as 10–18% with atrial septal defect, coarctation of the aorta and aortic stenosis (Burn et al. 1998).

Decisions about embarking on pregnancy with congenital heart disease need to balance the desire for children against the risk of mortality and morbidity. In the most serious conditions, women with Eisenmenger syndrome, primary pulmonary hypertension and inoperable cyanotic heart disease have a 30–50% risk of maternal mortality during pregnancy.

Valve disease

In general, pregnant women tolerate valvular regurgitation better than stenosis. This is because the reduced systemic vascular resistance improves forward flow and limits the effects of regurgitation. Stenosis, in contrast, creates a fixed impediment to the increase in cardiac output that accompanies pregnancy and labour, possibly precipitating pulmonary oedema and arrhythmias. In the UK, calcific degeneration of congenital bicuspid aortic valves is the leading cause of stenosis encountered in pregnancy. Pregnancy in women with artificial heart valves is a major dilemma. Most cardiologists currently recommend a tissue valve for women wanting to have children as, unlike mechanical valves, they avoid the need for anticoagulation, but they wear out more quickly.

Peripartum cardiomyopathy

Peripartum cardiomyopathy is a poorly understood condition, with an incidence of 1:1500 to 1:4000 live births. It has been defined clinically as the onset of cardiac failure with no identifiable cause in the last month of pregnancy or within 5 months after delivery, in the absence of heart disease before the last month of pregnancy (Demakis et al. 1971). It is associated with older maternal age, greater parity, black race, pre-eclampsia and multiple gestations (Veille 1984). Diagnosis rests on the echocardiographic identification of new left ventricular systolic dysfunction during a limited period around parturition, in a woman with symptoms and signs of heart failure and when other causes of cardiomyopathy have been excluded. All patients usually exhibit cardiomegaly on chest X-ray. Endomyocardial biopsy demonstrates myocarditis in up to 76% of patients, and may be necessary where the diagnosis is unclear. Treatment of peripartum cardiomyopathy includes diuretics to decrease pulmonary congestion and volume overload and vasodilators to reduce afterload. Hydralazine is the drug of choice prepartum, in addition to nitrates (Pearson et al. 2000). ACE inhibitors are the mainstay of treatment postpartum, even in mothers who are breastfeeding. The beta-blocker carvedilol has been shown to improve overall survival in pregnant women with dilated cardiomyopathy. Atrial arrhythmias should be treated with digoxin, which may also be used for its positive inotropic effect (Rahimtoola and Tak 1996). The benefits of class 3 (amiodarone) and class 4 (verapamil) agents needs to be balanced against their side-effects: fetal hypothyroidism and premature delivery, fetal bradycardia, heart block and hypotension respectively. Patients with poor cardiac function, as evidenced by an ejection fraction <35%, are at risk of thromboembolism and anticoagulation may be considered (Pearson et al. 2000).

After stabilisation of the mother's symptoms, in most cases induction and vaginal delivery can be attempted in consultation with consultant obstetrician and anaesthetic staff (George et al. 1997). The advantages of vaginal delivery are minimal blood loss, greater haemodynamic stability, avoidance of surgical stress and less chance of postoperative infection and pulmonary complications. Effective pain management is a necessity to avoid further increases in cardiac output from pain and anxiety.

Myocardial infarction

Ischaemic heart disease in pregnancy is uncommon, occurring in an estimated 1 in 10 000 deliveries (Hankins et al. 1985). Myocardial infarction is more common during the third trimester or puerperium of either the first or second pregnancies. occurs within 2 weeks of labour or delivery, mortality may be as high as 45% (Hankins et al. 1985). Patients typically present with ischaemic chest pain in the presence of an abnormal electrocardiogram (ECG) and elevated cardiac enzymes. Symptoms may often be masked or unclear during labour and delivery, and the ECG and cardiac enzymes can be insensitive. Cardiac-specific troponin I is a more sensitive indicator of myocardial infarction than creatinine kinase muscle–bone serum concentrations, which increase during normal labour (Shivvers et al. 1999).

Management of myocardial infarction must involve early coronary angiography. In the immediate postpartum period, spontaneous coronary artery dissection is the most common cause of myocardial infarction. The pathophysiological mechanisms responsible in the coronary arteries are similar to those responsible for aortic dissection, although the exact pathogenesis remains unclear. Most women with peripartum coronary artery dissection have no risk factors for coronary artery disease, but most affect the left anterior descending artery (McKechnie et al. 2001). Treatments include coronary stenting and emergency coronary artery bypass grafting.

Diabetes Mellitus (see Ch. 22 for management of the infant of a diabetic mother)

In the UK 2–5% of pregnant women have diabetes. Most of these pregnancies are due to gestational diabetes, and the rest are due to either type 1 or type 2 diabetes. The prevalence of type 2 diabetes is increasing throughout the world. Diabetes in pregnancy is associated with risks to the woman and to the developing fetus. Miscarriage, pre-eclampsia and preterm labour are more common in women with pre-existing diabetes. In addition, diabetic retinopathy can worsen rapidly during pregnancy. Stillbirth, congenital malformations, macrosomia, birth injury, perinatal mortality and neonatal hypoglycaemia are more common in offspring of women with diabetes.

Women with gestational diabetes have an increased risk of developing type 2 diabetes in later life. For this reason all women need postpartum assessment of glucose tolerance at more than 6 weeks postpartum. Advice on lifestyle and diet will reduce the future risk of diabetes.

In preconception counselling women with established diabetes should be informed that establishing good glycaemic control before conception and continuing this throughout pregnancy will reduce the risk of miscarriage, congenital malformation, stillbirth and neonatal death. These risks can be reduced, but not eliminated.

Overall the risk of congenital anomalies is three to five times greater in women with diabetes than in the general population and is related directly to the percentage of glycosylated haemoglobin at the time of conception (Stiete et al. 1995). The mechanism of this teratogenic effect is unclear, but appears to relate to glucose control and lipid levels.

Intrauterine fetal death

Despite advances in antenatal monitoring, women with poorly controlled diabetes still have an increased incidence of intrauterine fetal

	Plasma glucose	Plasma glucose
	Fasting	2 Hours
Normal	<5.4	<7.9
Glocose Intolerance	5.5–6.9mmol/l	8.0–10.9
Gestational Diabetes	>=7.0mmol/l	>=11.0mmol/l

Fig. 11.1 Revised World Health Organization criteria for 75 g oral glucose tolerance test during pregnancy.

death, especially beyond the due date. The underlying mechanism has not been elucidated, but relates to glucose control as reflected in the glycosylated haemoglobin.

Screening for gestational diabetes and impaired glucose tolerance

There are few conclusive data to support a screening programme for gestational diabetes in all age group mothers, as only small numbers of young and lean women will go on to develop gestational diabetes. What has been shown is that 75 g oral glucose loading is an appropriate mode of testing. If the screening test is abnormal, then the pregnant mother should go on to have an oral glucose tolerance test. The diagnostic criteria are shown in [Figure 11.1](#).

Management of diabetic pregnancy

Just as outside pregnancy the aim is to keep to a normal blood glucose level, diet, insulin and oral hypoglycaemic agents are the key components of diabetic management. A meta-analysis into large randomised controlled trials comparing oral hypoglycaemic and insulin demonstrates that there were no differences in glycaemic control or pregnancy outcomes, including incidence of babies that were large for gestational age, caesarean sections and increased birthweight ([Dhulkotia et al. 2010](#)).

Diet

The aim is to provide sufficient energy for both mother and fetus, which amounts to 30–35 kcal/kg of non-pregnant ideal body weight. Daily carbohydrate consumption should be in the region of 220–240 g, providing at least 45% of the necessary calorie intake. Detailed and ongoing advice from an experienced dietician is important to the success of dietary management. The first line of treatment for gestational diabetes is diet; if this approach fails, then hypoglycaemic therapy is considered.

Oral hypoglycaemic agents

If diet fails to control gestational diabetes, then metformin is the next line of treatment ([Rowan et al. 2008](#)). Metformin counteracts the excessive insulin resistance of gestational diabetes without risk of hypoglycaemia. It has been shown to be as effective as insulin in the management of gestational diabetes and with regard to pregnancy outcome ([Rowan et al. 2008](#)). Metformin does cross the placenta, but does not appear to be harmful to the developing fetus. Follow-up studies of offspring exposed to metformin in utero are ongoing, but after 2 years do not show differences compared with those exposed to insulin.

Insulin

Women with gestational diabetes who are not controlled by diet or metformin may need additional insulin. Increasingly, pen-type syringes are being used to deliver insulin, typically with three doses of short-acting insulin preprandially and one dose of a long-acting insulin at night. The newer insulin analogues appear suitable for pregnancy. Continuous subcutaneous insulin infusion may provide the best glucose control of diabetic pregnant women.

Labour and the puerperium

Preterm delivery is more common in diabetic pregnancy, and, if steroids are given to promote fetal lung maturity, the hyperglycaemic effect requires extra monitoring, but not usually a sliding scale of insulin.

Women with well-controlled diabetes, no vascular disease and a normally grown fetus appear to be at no more risk than non-diabetic counterparts and may be allowed to carry at least to the due date. With a macrosomic fetus and poor glucose control, early delivery may be contemplated to reduce the risk of stillbirth.

During labour women with type 1 diabetes can be treated with an insulin sliding scale, 10% glucose solution and hourly blood glucose monitoring. Once the baby is delivered the rate of insulin infusion should be reduced, or stopped if the woman has insulin-requiring gestational diabetes or type 2 diabetes. Insulin requirements fall back to prepregnancy levels as soon as the placenta has been delivered.

Breastfeeding and effects on glycaemic control

Women with insulin-treated pre-existing diabetes are at increased risk of hypoglycaemia in the postnatal period, especially when breastfeeding. Women with gestational diabetes should discontinue hypoglycaemic treatment after birth. Women with pre-existing type 2 diabetes who are breastfeeding can resume or continue to take hypoglycaemic agents following birth.

Thyroid disease

Hypothyroidism

Hypothyroidism affects 2–5% of all pregnancies. It is unusual to diagnose hypothyroidism for the first time during pregnancy, although it may develop as part of postpartum thyroiditis. The majority of women are therefore already on thyroxine replacement therapy when they attend for their first antenatal visit. It is good practice to check thyroid-stimulating hormone (TSH) levels every trimester and adjust requirements for thyroxine accordingly. Elevated TSH levels during the first trimester of pregnancy have been associated with an increased risk of mental and cognitive disturbance in children. It has been shown that children of women with hypothyroxinaemia but normal TSH during gestation had a delayed mental and motor function at 1 and 2 years of age. Therefore, not only TSH but also free thyroxine should be monitored, especially in the first half of pregnancy ([Haddow et al. 1999](#); [Pop et al. 2003](#)).

Taking into account the high prevalence of thyroid disorders during pregnancy and associated neonatal morbidity, an ongoing debate has developed as to the potential for routine screening of hypothyroidism in early pregnancy.

The aim of treatment for hypothyroidism is to keep TSH less than 2.5 mU/l in the first trimester and less than 3 mU/l in later

pregnancy. Thyroid function should be rechecked 6 weeks after delivery (Okosieme et al. 2008).

Thyrotoxicosis

Thyrotoxicosis occurs in 0.2% of pregnancies; Graves disease accounts for 95% of these cases. Both carbimazole (which is metabolised to methimazole) and propylthiouracil are used in the management of thyrotoxicosis during pregnancy. Less propylthiouracil crosses the placenta than methimazole. Carbimazole has been associated with cutis aplasia, although this is a very rare and tenuous association. Propylthiouracil also crosses into breast milk in lower quantities than does carbimazole. However, in practice it is doubtful whether there is any material difference between these two drugs, and treatment should be at a dose that maintains free thyroxine at the upper end of the normal range (Okosieme et al. 2008).

It has been reported that, in up to 10% of women who have had Graves disease, TSH receptor-stimulating antibodies cross the placenta and produce fetal tachycardia and transient neonatal thyrotoxicosis. Although the levels of these thyroid-stimulating antibodies can be measured in maternal blood, the assays are not readily available and measuring fetal heart rate in at-risk women is likely to be more useful. Treatment of fetal thyrotoxicosis is by increasing the maternal dose of antithyroid drugs until the fetal heart rate is in the normal range. Although rare, neonatal thyrotoxicosis has a significant mortality, hence early treatment is vital. Women who have been treated and 'cured' of Graves disease still have the autoantibodies and therefore neonatal thyrotoxicosis remains a possibility.

Hyperthyroidism should be distinguished from gestational transient thyrotoxicosis, which is due to the TSH receptor-stimulating effects of human chorionic gonadotrophin (hCG). This hCG-induced hyperthyroidism does not lead to clinical thyrotoxicosis and need not be treated with antithyroid drugs.

Neurological disorders in pregnancy

Epilepsy

Approximately 1 in 200 pregnant women have epilepsy. Not all women with epilepsy take antiepileptic drugs (AEDs), but, for those who do take AEDs, important clinical issues relate to the risks of uncontrolled seizures with the potential teratogenic effects of AEDs. Women who attend for pre-pregnancy counselling and who have been seizure-free for 2 years should be considered for withdrawal of anticonvulsant therapy, if appropriate for the cause of epilepsy.

Seizures can result in physical trauma or even death in the mother and fetus. Uncontrolled tonic clonic grand mal seizures result in metabolic and respiratory acidosis that is transferred to the fetus and may result in fetal bradycardia and intrauterine death (Katz et al. 2006).

Most women with epilepsy have already been diagnosed and need no further investigations. Women who develop seizures for the first time during pregnancy need to be investigated. Causes of seizures include cerebral vein thrombosis, thrombotic thrombocytopenic purpura, cerebral infarction, drug and alcohol withdrawal, hypoglycaemia, hyponatraemia, eclampsia and pseudoepilepsy. The largest prospective study of pregnant patients with epilepsy has shown that 58% of epileptic women experience no change in the frequency of their seizures during their pregnancy, about 18% have an increase in their seizure rate (EURAP Study Group 2006). The physiological changes in pregnancy, such as slower gastrointestinal absorption,

increased plasma volume, decreased protein binding, lack of sleep, poor compliance or nausea and vomiting of the first trimester, may all account for this. While the fetus is relatively resistant to short episodes of hypoxia and there is no evidence of adverse effects of single seizures on the fetus, status epilepticus has been associated with a 50% risk of fetal loss or handicap.

It is best for the mother and the baby, if the woman is on the lowest effective dose of AED to control their epilepsy during pregnancy.

The mechanism by which AEDs cause congenital anomalies appears to be multifactorial, with some degree of genetic vulnerability not yet defined.

The underlying risk of malformation for any one drug is about 6–7% (i.e. about two- to threefold the background malformation rate). Unfortunately, the risk rises at least additively with each additional anticonvulsant; thus it is approaching 20% if a woman is on three anticonvulsants, and with some combinations the increase in risk is even greater.

Despite the risk of teratogenicity it is important to emphasise to women with epilepsy that uncontrolled seizures can be more hazardous to the fetus than the risks associated with anticonvulsants. The risks of congenital abnormalities may be minimised by maintaining women on the lowest possible dose of drug that keeps them seizure-free, and by the use of single rather than multiple AEDs.

Folic acid 5 mg once daily periconception and throughout pregnancy has been suggested to reduce the risk of malformations and neurodisability, but evidence is currently lacking.

Antiepileptic drugs

Carbamazepine

A total of 1% of carbamazepine-exposed infants have spina bifida (Rosa 1991). There is also an increase in the rate of craniofacial defects and fingernail hypoplasia.

Phenytoin has been associated with microencephaly, mental retardation, growth deficiency and congenital heart defect.

Sodium valproate carries a 1–2% risk of neural tube defects occurring in the fetus. It is also associated with congenital heart defects. Cognitive function is probably affected by valproate, though the size of the effect is uncertain. There is also concern that there may be a link between valproate exposure and autism (Williams and Hersh 1997). Further prospective research is needed to identify the link between maternal valproate use and neurodisability in the offspring.

Lamotrigine

Lamotrigine is the most extensively investigated of the newer AEDs. Pharmacokinetic changes are pronounced: on average, plasma concentrations decreased by 68% during pregnancy, with a wide individual variability (Pennell et al. 2004). A decline in plasma concentration of lamotrigine has been associated with breakthrough seizures in up to 75% of pregnant women on monotherapy (de Haan et al. 2004). Some authorities believe women with epilepsy on lamotrigine should have their serum levels checked and the dose of lamotrigine adjusted accordingly. A prospective pregnancy data registry has also shown that patients on lamotrigine require more frequent dose adjustment during pregnancy (Vajda et al. 2006).

Very limited or no information is available on possible changes in disposition of the other new-generation AEDs (e.g. gabapentin, vigabatrin).

Early detailed ultrasound should be offered to all mothers with epilepsy in order to exclude neural tube defects and life-threatening congenital heart anomalies.

There is a theoretical risk of vitamin K deficiency in the neonates of mothers who take anticonvulsants during pregnancy. It was formerly suggested that vitamin K supplements be given to the mother in the last few weeks of pregnancy and to the neonate at birth to prevent haemorrhagic disease of the newborn, but this recommendation is not current. Newborn babies of mothers taking anticonvulsants should receive intramuscular vitamin K.

The risk of an epileptic seizure is approximately doubled in labour because of exhaustion, pain and lack of sleep; therefore, the usual doses of anticonvulsant should be given. Caesarean section is only indicated for obstetric reasons. If the dose of anticonvulsant has been increased during the pregnancy a reduction should be made after delivery.

Breastfeeding

AEDs pass into breast milk. The concentration of drug depends on the pharmacokinetics in the mother and pharmacokinetics and pharmacodynamics in the baby. The mother should be informed about the possibility of drug effects on breastfeeding but not discouraged from breastfeeding (Tomson 2005).

Stroke

Cerebrovascular accidents (Stroke) during pregnancy or the puerperium are an important cause of maternal death and serious maternal morbidity (Kittner et al. 1996). The reported incidence of Stroke in relation to pregnancy varies from 3.8 to 26 cases per 100 000 deliveries or pregnancies, depending on the population studied (Jaigobin and Silver 2000).

The majority of Stroke events occur postpartum and therefore do not have a direct impact on neonatal health. Uncontrolled high blood pressure and pre-eclampsia place a woman at increased risk for Stroke. While strokes are rare in women of childbearing age, with gradually decreasing maternal mortality rates over the past 20 years, they now account for over 10% of the total number of maternal deaths in the UK (CEMD 2001). Strokes are defined as acute ischaemic or haemorrhagic events causing the onset of focal neurological symptoms.

Subarachnoid haemorrhage

The incidence is 1–2 per 10 000, with an overall mortality of between 27% and 40% (Treadwell et al. 2008). Most cases of subarachnoid haemorrhage are due to ruptured cerebral aneurysms, and typically present with thunderclap headache, vomiting, seizures or reduced level of consciousness. Presentation in pregnancy may be confused with eclampsia, and the diagnosis should be confirmed with neuroimaging or cerebrospinal fluid analysis. The relative risk of intracerebral haemorrhage during pregnancy and 6 weeks postpartum has been reported to be 5.6 times that of the non-pregnant patient, and 50% of all aneurysmal ruptures in women below the age of 40 years are pregnancy-related. Surgical treatment after aneurysmal subarachnoid haemorrhage during pregnancy improves both maternal and fetal outcome, and management should generally follow the same course as for the non-pregnant population (Dias 1994). The mode of delivery for women with arteriovenous malformation or aneurysms is still contentious. If the arteriovenous malformation or aneurysm is successfully operated on, then vaginal delivery is appropriate. The risk of recurrent haemorrhage during labour may be reduced by epidural anaesthesia, minimising pushing

in the second stage, and by performing an instrumental delivery if required.

Cerebral venous thrombosis

Cerebral venous thrombosis (CVT) occurs most commonly during the puerperium. It has an incidence of 1 per 10 000 deliveries in the developed world but in the developing world it is the most common cause of stroke, with an incidence of 40–50 per 10 000 deliveries (Canhao et al. 2005). It is typically associated with infection and dehydration, though there are many other recognised causes. Occlusion of the cerebral cortical veins can result in venous infarction with associated focal neurological symptoms and signs. Cavernous sinus thrombosis may also lead to a painful eye and sometimes exophthalmos. The risk of peripartum CVT increases with hypertension, advancing maternal age, caesarean delivery, associated infections and excess vomiting during pregnancy (Lanska and Kryscio 2000). The diagnosis of CVT is made by CT or MRI.

The death rate from all-cause CVT is 2–10%, although mortality is significantly less for pregnancy-associated CVT (Cantu and Barinagarrementeria 1993). CVT should be treated with therapeutic LMWH with factor Xa monitoring (Bates et al. 2004).

Multiple sclerosis (MS)

This disease is relatively common, with an incidence of approximately 1:1000, and it tends to occur during the childbearing years, with a peak incidence at 30 years of age. The cause of MS is unknown and the course is unpredictable. Common symptoms include the acute onset of diplopia, vertigo, gait instability, bladder incontinence, loss of vision and fatigue. The common neuropathological lesion is a plaque demonstrating myelin loss and gliosis associated with inflammatory infiltrates. There are retrospective and prospective (Roullet et al. 1993) data that suggest improvement of MS during pregnancy and fewer relapses (Korn-Lubetzki et al. 1984); however this benefit is largely reversed during the first 3 postpartum months when there are higher reports of relapses (Confavreux et al. 1998).

Spinal and epidural anaesthesia appear to be safe in labour, despite a diagnosis of MS. There is no long-term effect of pregnancy or breastfeeding on the course of MS; however the children of women with MS have a 30-fold increased risk of developing the condition (a 3% risk compared with the background rate of 0.1% in the general population) (Sadovnick 1984).

Current MS therapy includes intravenous corticosteroids and other immunosuppressive agents (i.e. cyclophosphamide) for acute relapses and immunosuppressive drugs (azathioprine, ciclosporin A, cyclophosphamide and methotrexate – although the last two are contraindicated in pregnancy) for long-term treatment. The two immune modulator pharmacological agents which are mainly used for relapsing–remitting-type MS are interferon-beta and glatiramer (a polymer) (Janssen and Genta 2000). It is generally recommended that interferon therapy should be discontinued before conception. Available data suggest no increased risk of adverse fetal or pregnancy outcomes associated with glatiramer acetate use (Coyle 2009).

Labour and delivery

Delivery is not more complicated in MS patients than in women without MS, and the mode of delivery is decided strictly on obstetrical criteria. Maternal exhaustion seen in the second stage can be managed with operative vaginal delivery. MS patients who have recently received long-term corticosteroid therapy or who are on

low-dose corticosteroid therapy at the time of delivery may have adrenal insufficiency and should be given supplemental corticosteroids.

Breastfeeding

Systemically administered steroids appear in human milk in a ratio of 1:10 (breast milk:maternal serum) and have not been found to affect the neonatal pituitary–adrenal axis in doses of prednisolone up to 40 mg. Azathioprine is not found in breast milk and the benefits of breastfeeding exceed potential risks associated with ciclosporin A. It is not known whether interferon-beta is secreted into breast milk. The Committee on Drugs of the American Academy of Pediatrics advises that methotrexate should be avoided during lactation owing to potential immune suppression, neutropenia, adverse effects on growth and carcinogenesis ([American Academy of Pediatrics Committee on Drugs 2001](#)). Breastfeeding is unrestricted during intravenous immunoglobulin therapy and there is no known negative effect on the developing immune system of the newborn baby.

Renal disease and pregnancy

Most women with chronic kidney disease who become pregnant have mild renal dysfunction and pregnancy usually succeeds without affecting renal prognosis. In general, women with serum creatinine (sCr) levels of less than 125 $\mu\text{mol/l}$ have good obstetric outcomes and a good long-term renal prognosis. Those women with moderate (sCr > 125 < 180 $\mu\text{mol/l}$) or severe (sCr > 180 $\mu\text{mol/l}$) renal insufficiency do less well, with an increased risk of an accelerated decline in renal function and poor pregnancy outcome correlated with the level of renal impairment. When sCr is greater than 180 $\mu\text{mol/l}$, more than 50% of women develop pre-eclampsia, especially if there is associated hypertension. One in three women with sCr > 180 $\mu\text{mol/l}$ develop end-stage renal failure within 1 year of delivery ([Davison 2001](#)). The main parameters that can be controlled during pregnancy and may improve pregnancy outcome are the management of associated hypertension, prevention of recurrent urinary tract infections (UTIs) with antibiotic prophylaxis and prevention of thrombosis in women with proteinuria >1 g/24 hours.

Asymptomatic bacteriuria

The incidence of asymptomatic bacteriuria is in the region of 5%. *Escherichia coli* is the most commonly isolated pathogen and is present in 80–90% of UTIs and up to 95% of acute pyelonephritis ([Connolly and Thorp 1999](#)). Up to 30% of pregnant women with untreated bacteriuria will go on to develop pyelonephritis. Under these circumstances there is a risk of preterm delivery and low birthweight ([Ovalle and Levancini 2001](#)). An association between untreated UTI in pregnancy and risk of neonatal mental retardation has also been reported ([McDermott et al. 2000](#)).

Acute pyelonephritis

Pyelonephritis has been shown to affect 1.3% of pregnancies, with *E. coli* being the most common pathogen. The diagnosis is likely if there are symptoms of a UTI together with a high fever, nausea, vomiting, rigors and renal-angle pain and tenderness. The patient should be admitted to hospital and treated with intravenous broad-spectrum antibiotics. Ceftriaxone, because of its safety and negligible side-effects, has been suggested as an effective antibiotic for acute antepartum pyelonephritis ([Sharma and Thapa 2007](#)).

Renal transplantation and pregnancy

Pregnancy is becoming increasingly common in women who have been the recipients of renal transplants. About 1 in 50 women of childbearing age with renal allografts become pregnant ([Davison 2001](#)). There is an increased incidence of maternal hypertension, preterm delivery (45–66%) and fetal growth restriction (40%) that reflects the level of renal function and coexistent complications such as hypertension, proteinuria and UTIs.

To prevent rejection of the renal allograft immunosuppressive therapy with prednisolone, ciclosporin A, azathioprine, tacrolimus, sirolimus and mycophenolate mofetil (MMF) has been used. All these drugs cross the placenta and enter the fetal circulation. MMF is teratogenic and should be replaced with azathioprine during pregnancy. [The European Best Practice Guidelines \(2002\)](#) also recommend avoiding sirolimus during pregnancy.

Breastfeeding

Breastfeeding for transplant-recipient mothers remains an area in which recommendations are evolving. The lack of reported adverse effects, together with the documented benefits of breastfeeding, outweigh the theoretical risks.

Haematology

Physiological changes during pregnancy

Plasma volume increases progressively throughout pregnancy so that by 36 weeks' gestation it is 50% greater than in the non-pregnant state. There is also an increase in the red cell mass, but the expansion in plasma volume is far greater than the increase in red cell mass, hence the net effect is a fall in haemoglobin concentration, haematocrit and red cell count. Despite this haemodilution, there is usually no change in mean corpuscular volume or mean corpuscular haemoglobin concentration. Pregnancy causes a two- to threefold increase in the requirement for iron, and a 10–20-fold increase in folate requirements to meet the demands of the expanding red cell mass, fetus and placenta. The lower limit of normal for haemoglobin concentration in the non-pregnant female is 11.5–12 g/dl. In pregnancy, levels below 10.5 g/dl may be abnormal, although in certain situations, such as multiple pregnancies, the physiological dilution of haemoglobin may cause even lower concentrations of haemoglobin.

Iron-deficiency anaemia

On a global basis iron-deficiency anaemia is still a leading cause of maternal morbidity and mortality. In developed countries significant iron-deficiency anaemia is uncommon, although most women are routinely prescribed supplements of iron and folic acid. There is no consensus about the value of giving prophylactic iron to a population which is well nourished. This is not the case in the developing world.

Folate-deficiency anaemia

Folic acid deficiency is the major cause of megaloblastic anaemia in pregnancy; vitamin B₁₂ deficiency is very rare, except in developing countries or strict vegans. Folate deficiency is more likely if the woman is taking AEDs or if she suffers from haematological conditions such as haemolytic anaemia and thalassaemia. Diagnosis of folate deficiency should be confirmed by the measurement of serum

and red cell folate levels (it should be noted that the normal range in pregnancy is lower than in non-pregnant women). All women planning pregnancy are now advised to take 400 µg/day folate periconceptionally to lower the risk of neural tube defects and other fetal abnormalities and this reduces the risk of folate deficiency still further. In addition, women who have had a previous fetus with a neural tube defect and women taking anticonvulsants or sulfasalazine and who have diabetes are advised to take 5 mg/day folate periconceptionally.

Haemoglobinopathies

The most common types of haemoglobinopathies include sickle-cell disease and thalassaemia. Their incidence varies according to ethnicity.

Sickle-cell disease

Most women with sickle-cell disease will be aware of the diagnosis before they become pregnant. Haemoglobin electrophoresis is however part of routine antenatal screening in pregnancy in the UK. Sickle-cell crises may occur in any trimester, but dehydration in early pregnancy due to hyperemesis may be an exacerbating factor. Pregnant women with sickle-cell disease are at increased risk of miscarriage, preterm labour, pre-eclampsia and intrauterine growth restriction. Prepregnancy counselling and screening of the father are vital to give the couple an accurate estimate of the risk of having an affected child.

Thalassaemias

There are two types of thalassaemia arising from abnormal globin synthesis, leading to alpha- or beta-thalassaemia. Alpha-thalassaemia major is not compatible with life, but carriers may be asymptomatic and can become anaemic during pregnancy. Beta-thalassaemia major is inherited when both parents are carriers. These individuals need lifelong transfusions and have complications as a result of iron overload. Thalassaemia trait is usually asymptomatic but may cause significant anaemia during pregnancy. Prenatal diagnosis of both parents is necessary to identify a fetus at risk of inheriting thalassaemia major.

Gestational thrombocytopenia and immune thrombocytopenic purpura

Gestational thrombocytopenia is a benign condition that requires no intervention. The platelet count falls during a normal pregnancy and in about 10% of women falls $<100 \times 10^9/l$ by term.

Idiopathic thrombocytopenic purpura is diagnosed when thrombocytopenia occurs in the absence of other haematological abnormalities or clinical features such as splenomegaly or lymphadenopathy. Antibodies against platelet surface result in destruction of the platelets. Have the facility to identify antiplatelet antibodies, but usually the diagnosis of idiopathic thrombocytopenic purpura follows exclusion of other causes of thrombocytopenia. The platelet count may increase with corticosteroids, or, in resistant cases, intravenous gamma-globulin can be infused. The risk of thrombocytopenia or haemorrhage in the fetus from transplacental passage of IgG antiplatelet antibodies is low ($<5\%$).

Malignant disease and pregnancy

The incidence of malignant neoplasms in women of reproductive age has increased over the past decade and is still rising.

Haematological malignancies, such as lymphomas, have a peak incidence in young adulthood and therefore on occasion will invariably coincide with pregnancy. During pregnancy, difficult decisions need to be made between the maternal benefits of prompt treatment of the malignancy and the adverse effects of this treatment on the developing fetus.

Care of a pregnant patient with a malignancy should be individualised and a multidisciplinary team approach should be established (Pentheroudakis and Pavlidis 2006). If chemotherapy is the treatment of choice, the interests of the fetus are best served by delaying treatment until the second trimester and also too close to delivery (Cardonick and Iacobucci 2004). In general, radiation should be avoided during pregnancy. The placenta should be sent to pathology for all patients with malignancies diagnosed during pregnancy as occasionally cancers, especially melanoma, cross the placenta.

Long-term follow-up of offspring exposed to chemotherapy is essential, especially regarding secondary malignancies and fertility. Drug metabolism of chemotherapeutic agents in pregnancy may warrant higher doses of some medications and lower doses of others. Prospective data are needed to guide such management and, given the rarity of cancers in pregnancy, international collaboration is warranted.

Respiratory disease

During pregnancy, women breathe more deeply rather than more quickly and, at some point, this physiological adaption makes most women develop a subjective feeling of breathlessness. This normal symptom of pregnancy is sometimes difficult to differentiate from pathological breathlessness.

Asthma

The most commonly encountered respiratory disease in pregnancy is asthma, which affects 3% of the childbearing population (Littlejohns et al. 1989). There is no consistent effect of pregnancy on asthma, with some individuals showing improvement, others deterioration and some no change.

The management of asthma in pregnancy is the same as in non-pregnant women. Inhaled steroids are preferable to oral treatment, but oral prednisolone should not be withheld from a pregnant patient if required to treat severe asthma. The National Institute of Child Health and Human Development Maternal Fetal Medicine Units Network Asthma Study found a trend towards an increased incidence of low birthweight among infants born to women exposed to oral steroids (Schatz et al. 2004). There is no evidence of any teratogenic effects with the conventional drugs used to treat asthma, including β -agonists, oral or inhaled steroids, sodium cromoglycate and theophyllines (Bracken et al. 2003; Schatz et al. 2004). Leukotriene receptor antagonists (montelukast and zafirlukast) have been assigned a pregnancy category B, since animal studies have not demonstrated a risk to the fetus, but to date there are no adequately powered studies in pregnant women (Spector 2001). For some women with asthma the clinical benefit of leukotriene receptor antagonists will outweigh the remote possibility of fetal harm.

Regional anaesthesia is preferable to general anaesthesia because of the increased risks of postoperative chest infection following intubation. Women who suffer with asthma should be encouraged to breastfeed, as there is some evidence that it may help to prevent atopic problems in their offspring. None of the drugs used in the management of asthma are contraindicated in breastfeeding. The 4% background risk of a child developing asthma is increased

approximately two- to threefold if one parent has asthma, particularly if he or she is atopic.

Cystic fibrosis

Cystic fibrosis is an autosomal recessive disorder arising from a defect on chromosome 7. The prevalence of the abnormal gene is about 4% in many white populations, with an incidence of homozygous cystic fibrosis of one in 2500 livebirths (Dodge et al. 1997). The median survival of women with this condition has changed from the early teens to the fourth decade over the last 50 years. Thus women with cystic fibrosis are increasingly surviving into the reproductive age. The ability of the mother to carry the pregnancy to term appears to be primarily related to her prepregnancy lung function, although severe underweight is also an important risk factor. Ideally the parents should seek preconception counselling for advice on genetic and prenatal diagnosis, compliance with medical therapy, optimisation of lung function, nutritional assessment, psychological assessment, medication review, venous access for antibiotic therapy, mode of delivery and breastfeeding.

If the mother is generally fit there is little evidence to suggest that the fetus will be affected by the mother's cystic fibrosis, though there is an increased risk of preterm delivery (Odegaard et al. 2002). Patients with a low forced expiratory volume in 1 second (less than 50%) should be managed in tertiary centres by a multidisciplinary team as this level of pulmonary dysfunction carries a significant risk of maternal mortality from respiratory failure (Lau et al. 2010).

Rheumatological disorders

Rheumatoid arthritis

Pregnancy was thought to confer a favourable outcome on women with rheumatoid arthritis, but a significant minority (approximately 20%) deteriorate during pregnancy. There is an increased risk of preterm birth, pre-eclampsia and caesarean section in mothers with rheumatoid arthritis (Skomsvoll et al. 1998; Reed et al. 2006). The risk of relapse is increased in the 3 months postpartum, but the majority of women do not report a relapse.

Management with prednisolone, sulfasalazine, non-steroidal anti-inflammatory drugs (NSAIDs) and hydroxychloroquine (Costedoat-Chalumeau et al. 2003) form the mainstay of treatment of active rheumatoid arthritis. Regular use of NSAIDs should be avoided in the third trimester to prevent premature closure of the fetal ductus arteriosus. 5-Aminosalicylic acid preparations include mesalazine, olsalazine, balsalazide and sulfasalazine. They are folic acid antagonists and should be given throughout pregnancy with folic acid 5 mg daily. Methotrexate should be avoided for 3 months prior to conception. Folic acid should be continued throughout pregnancy for women who have taken methotrexate prior to pregnancy. Leflunomide also has teratogenic potential and should be avoided in pregnancy and washed out of the mother with cholestyramine prior to conception.

Biological agents like intravenous immunoglobulin, etanercept, infliximab and anakinra carry acceptable US Food and Drug Administration ratings (B) for use in pregnancy. These immunoglobulins are not transmitted to the fetus until relatively late in pregnancy (Hyrich et al. 2006; Salmon and Alpert 2006). Less information is available about adalimumab, but it probably behaves similarly to infliximab. There is no reliable information about abatacept in humans. Rituximab is potentially less safe because reversible fetal cytopenias, including B-cell depletion, have

occurred in infants of mothers who are given this drug during pregnancy.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) affects women of childbearing age and fertility is generally conserved, except when renal function is seriously compromised (creatinine clearance <50 ml/min), the disease is active, or when amenorrhoea has been induced by cytotoxic therapy. The risk of flare during pregnancy relates to the level of maternal disease activity in the 6–12 months before conception (Mintz et al. 1986).

SLE flares during pregnancy and postpartum are generally mild or moderate, with a predominance of cutaneous, articular and minor haematological manifestations (thrombocytopenia) (Mintz et al. 1986). Lupus affecting the kidneys and the brain presents the most challenging problems for the mother and the well-being of the offspring. Management of these complications requires specialist help from rheumatologists who are expert in the management of SLE.

Pregnancies in women with lupus nephritis, but less so with other forms of SLE, are at increased rate of pregnancy loss, premature birth, intrauterine growth restriction and pre-eclampsia.

Pregnant women with SLE who have anti-Ro/SS-A and anti-La/SSB antibodies have a 1:50 risk of offspring affected by neonatal lupus (Brucato 2008). Neonatal lupus can present as fetal heart block, cutaneous lupus or hepatic involvement. Women who have had one infant affected by neonatal lupus have a 1:20 risk of another affected offspring. In all cases where the mother carries the antibodies, fetal medicine doctors must screen for heart block (all degrees of heart block, first, second and third degree) from 16 to 32 weeks' gestation. Maternal steroids and intravenous immunoglobulin have been tried with some success to prevent progression of fetal heart block (David et al. 2010).

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is characterised by the presence of antiphospholipid antibodies in the setting of either vascular thrombosis or pregnancy complication. The pregnancy complications include repeated pregnancy losses, fetal growth restriction and pre-eclampsia. Women with APS can also be affected by infertility, and maternal thrombosis. Treatment with heparin can reduce the risk of pregnancy loss to less than 30% (Empson et al. 2002). The pathophysiology of the disease includes thrombosis and inflammation via the complement cascade that contributes to poor pregnancy outcomes.

Current recommendations, based on existing data and expert opinion, suggest that women with no history of thrombosis or pregnancy complication should receive no treatment or treatment with low dose aspirin (LDA) alone during pregnancy; women with antiphospholipid antibodies and a history of pregnancy complication should receive prophylactic-dose LMWH with LDA; women with antiphospholipid antibodies and a history of vascular thrombosis should receive full-dose LMWH and LDA. The increased risk of thrombosis in the postpartum period requires treatment with anticoagulation for up to 6 weeks postpartum and is also recommended for patients with APS (Derksen et al. 2004).

Liver disease

There are two forms of liver disease specific to pregnancy that are thought to pose a particular risk to the mother and/or baby: obstetric cholestasis and acute fatty liver of pregnancy.

Intrahepatic cholestasis of pregnancy/obstetric cholestasis

Obstetric cholestasis is a disease of pregnancy with a prevalence of <1% but more commonly seen in south American, Chinese and Scandinavian women (Milkiewicz et al. 2002). It usually presents in the third trimester of pregnancy with itching mainly of palms of the hands and soles of feet. The abnormal biochemical finding that may alert the obstetrician to this condition is a rise in the liver transaminases in >80% of patients, raised bilirubin in <25% and raised serum bile acids in the majority of affected women (Milkiewicz et al. 2002). The synthetic function of the liver remains normal.

The aetiology of the condition is not understood, but it appears to have both genetic and environmental components. It seems at least in part to be induced by high levels of oestrogen and progesterone, as symptoms may recur if an affected woman subsequently uses combined oral contraception. In one study, a third of pregnancies affected by obstetric cholestasis were complicated by 'fetal distress' (the nature of which is often not simply hypoxia – see later) and almost 2% were associated with intrauterine death (Lammert et al. 2000; Glantz et al. 2004). Jaundice is uncommon, even though liver function tests are commonly abnormal. Women affected by obstetric cholestasis should be offered ursodeoxycholic acid (URSO) to relieve their pruritus and this often corrects biochemical abnormalities. URSO makes bile acids more hydrophilic and aids their excretion. It is not licensed for use in pregnancy, but there are no reports of harm associated with its use.

It is not known why there appears to be an increased risk of stillbirth with obstetric cholestasis, but it has been suggested that if the placenta has similar difficulty with bile acid transport as the maternal liver (perhaps by inheriting the same defect), then bile acid levels in the fetus will rise to dangerously high levels. Certainly, bile acids have been shown to cause asystole in beating cardiomyocytes in tissue culture. If this in vitro model is correct, it is possible that URSO may also protect the fetus, but this has not been established. There are concerns about sudden fetal death associated with obstetric cholestasis and some centres advocate delivery around 37 weeks. Prospective trials are needed to assess whether complications associated with early delivery are justified by the decreased risk of stillbirth. Maternal liver function and pruritus usually resolve within a few days of delivery.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare complication of pregnancy with an estimated prevalence of around 1 per 5000 pregnancies. AFLP occurs in the second half of pregnancy, usually close to term. Presentation is typically with nausea. There are often hypertension and proteinuria and the condition is associated with pre-eclampsia, multiple pregnancy and maternal obesity. It is also more common when the fetus is male (ratio 3:1). Transaminases are elevated, as is alkaline phosphatase (above the normal upper limit for pregnancy), but the biochemical findings that generally distinguish AFLP from pre-eclampsia are a much higher elevation of uric acid and elements of liver dysfunction, e.g. hypoglycaemia, prolonged INR and hypoalbuminaemia. Jaundice is a late feature of the disease. MRI or CT scanning is unhelpful with the diagnosis. Liver biopsy is diagnostic (showing microvesicles of fat in the hepatocytes), but is risky if clotting is abnormal and under these circumstances is therefore not recommended. Precise diagnosis is less important than prompt delivery, which is usually mandated by deteriorating maternal and fetal condition.

General supportive measures include control of hypertension and correction of hypoglycaemia and deficiencies in clotting factors. The fetus should be delivered without delay. Maternal and neonatal mortality associated with AFLP is improving, due to earlier diagnosis and prompt delivery. If the mother survives, full recovery is the rule (Pereira et al. 1997). On occasion, mothers with AFLP develop the condition because the fetus they are carrying is affected with a long-chain fatty acid disorder, 3 hydroxyacyl-coenzyme-A dehydrogenase deficiency (Treem et al. 1994).

Viral hepatitis

Infection with hepatitis viruses A, B, C and D produces a clinical picture in the pregnant woman very similar to that outside pregnancy. Management of vertical transmission of hepatitis A, B and C to the neonate is described elsewhere. Hepatitis E, which is epidemic in some areas of South-east Asia, differs in that this usually mild disease carries a significant risk of maternal morbidity and mortality during pregnancy. The reasons for this change in pathogenicity are unclear.

Gastroenterology

Inflammatory bowel diseases

Inflammatory bowel diseases (IBDs), which include ulcerative colitis and Crohn disease, are more common in younger people and women. Active IBD at the time of conception or during pregnancy significantly increases the risk of preterm delivery and low-birthweight offspring (Dominitz et al. 2002). Risk factors for a poor pregnancy outcome include a history of IBD surgery and increasing maternal age (Mahadevan et al. 2007).

There is a risk of disease flare postpartum, but not regularly enough to recommend pre-emptive immunosuppression. Breast-feeding does not influence disease activity in the postpartum period (Klement et al. 2004).

Pharmacological treatment

Pharmacological treatments that are used for treatment of IBD and include corticosteroids, 5-aminosalicylic acid preparations such as sulfasalazine, azathioprine, ciclosporin A, tacrolimus, infliximab and antitumour necrosis factor (Moffatt and Bernstein 2007).

Biliary tract disease

Weight gain and hormonal changes predispose pregnant women to biliary sludge and gallstone formation. Oestrogen increases bile lithogenicity whereas progesterone impairs gallbladder emptying. The reported incidence of biliary sludge and gallstones during pregnancy ranges from as high as 31% to 12%. Most women are asymptomatic and no therapy is indicated. However, when cholelithiasis becomes symptomatic surgical intervention may be required. Symptoms of active gallstone disease are similar to those of non-pregnant women with differential diagnoses that include hyperemesis, idiopathic pancreatitis and peptic disease.

Ultrasonography is a sensitive test for cholelithiasis but is less sensitive for the detection of common bile duct stones and dilated biliary ducts. Magnetic resonance cholangiopancreatography can be safely used during pregnancy. In the pregnant patient, therapeutic endoscopic retrograde cholangiopancreatography has become the standard of care when treating choledocholithiasis.

Common gastrointestinal symptoms in pregnancy

Gastro-oesophageal reflux is common in pregnancy, especially in the third trimester. Peptic ulcer disease appears to be less common in pregnancy. Histamine receptor antagonists and proton pump inhibitors are safely used in pregnancy. *Helicobacter pylori* eradication therapy may be appropriate if simple measures have failed.

Nausea and vomiting affect approximately 50% of pregnant women in the first trimester. More severe and protracted vomiting occurs in a minority of women and can lead to hyperemesis with ketosis, dehydration and weight loss. Hyperemesis gravidarum occurs in <1% of pregnancies. The main risks are dehydration and thrombosis, and very rarely Wernicke's encephalopathy due to vitamin B₁ (thiamine) deficiency. The mainstay of treatment is to correct hypovolaemia, electrolyte imbalances and vitamin deficiencies. Antiemetics such as dopamine antagonists (metoclopramide, domperidone), phenothiazines (chlorpromazine, prochlorperazine), anticholinergics (dicyclomine) or antihistamine H₁-receptor antagonists (promethazine, cyclizine) can be safely used. In women with severe hyperemesis who have not responded to one of the antiemetic therapies mentioned above, there have been promising results reported with both corticosteroids and 5-hydroxytryptamine-3 receptor antagonists. Furthermore, corticosteroids appear to be effective in some women with hyperemesis gravidarum. Thromboprophylaxis with LMWH is necessary for those admitted to hospital.

Psychiatric diseases

Depression can occur both antenatally and postpartum. Postnatal depression includes a spectrum from postpartum 'blues', which affects 50% of women and is a mild, self-limiting condition. It is characterised by symptoms such as weeping, sadness, irritability and anxiety. The symptoms usually peak around the fourth day and resolve by the 10th day. In contrast, significant mental illness leading to suicide now accounts for at least 10% of all maternal deaths in the UK ([Confidential Enquiry into Maternal Death in the UK 2002](#)). This disturbing statistic is made more shocking by the violent nature of the suicides.

Postpartum depression

One in eight new mothers develop postpartum depression. Women who have had one episode of postpartum depression have a 1:4 risk of recurrence. Many of these women will suffer a severe depressive illness and 2% will see a psychiatrist during the first postpartum year. Very rarely (2:1000), puerperal psychosis will develop ([Vesga-Lopez et al. 2008](#)).

Postpartum depression usually has an insidious onset within the first 3–6 months after childbirth. The mother's depressive thoughts typically centre on feelings of inadequacy in the maternal role and concerns for neonatal well-being. The signs and symptoms include increasing sleeplessness, loss of appetite and lack of energy. Maternal thyroid function should be checked, as postpartum thyroid disease is associated with depression.

During pregnancy, untreated maternal depression has been associated with adverse effects on the fetus, including preterm labour, low birthweight, decreased Apgar scores, elevated levels of fetal stress hormones and changes in neurobehavioural function (e.g. hypotonia and motor difficulties) ([Marcus 2009](#)). One study found that the relapse rate of major depression was 68% in women who discontinued antidepressant medication, compared with 26% in

women who continued medications. Depression may also affect the mother's ability to care for herself and obtain appropriate prenatal care.

An epidemiological study of more than 15 000 infants during a period of nearly 30 years found that certain birth defects occurred more frequently in mothers taking specific selective serotonin reuptake inhibitors (SSRIs; e.g. sertraline and occurrence of omphalocele and/or septal defects; paroxetine and right ventricular outflow tract obstruction defects). However, the overall absolute risk of congenital abnormality with SSRIs seems small ([Cantor et al. 2009](#)). A 1.5- to twofold increased risk of cardiac defects (particularly ventricular septal defects) was reported in infants exposed to paroxetine in the first trimester ([Cantor et al. 2009](#)). Although subsequent studies did not confirm this association, the American College of Obstetrics and Gynecology (ACOG) still recommends a fetal echocardiogram for fetuses exposed to paroxetine ([ACOG Committee 2006](#)). SSRIs taken during pregnancy increased rates of persistent pulmonary hypertension of the newborn (PPHN) to 2.4 times that of infants of mothers who were not taking an SSRI ([Kallen and Olausson 2008](#)). However, PPHN, although a serious and potentially life-threatening condition, did not occur in the majority (nearly 99%) of infants with late in utero exposure to SSRIs ([Cantor et al. 2009](#)). This is another situation where treatment of the maternal condition needs to be balanced against potential harm to the fetus.

Third-trimester exposure to SSRIs has also been associated with 'transient neonatal complications' such as increased muscle tone, irritability, jitteriness, disrupted sleep and abnormal breathing ([ACOG Committee 2006](#)). Another study found that late-term SSRI exposure was associated with increased rates of prematurity, decreased birthweight and size and other anomalies ([Cantor et al. 2009](#)).

Sertraline and paroxetine have been reported to have undetectable levels in the breastfed infant whose mother is taking these drugs ([Moretti 2009](#)). Thus, these medications may be a good choice for lactating women.

Treatment of bipolar disorders with lithium, valproate, carbamazepine, lamotrigine and oxcarbazepine has been associated with increased teratogenicity (in particular with cardiac and neural tube malformations) ([Dodd and Berk 2006](#)). Lithium is associated with a rare increased risk of Ebstein's anomaly, which affects 1:1000 infants exposed to lithium in utero. Maternal need for treatment with lithium needs to be balanced against this rare consequence. Renal excretion of lithium increases significantly during the third trimester, which usually necessitates an increase in maternal dose and a consequent reduction postpartum. Lithium is secreted into breast milk and has been associated with adverse neonatal events such as lethargy, hypotonia, cyanosis and electrocardiogram changes ([Menon 2008](#)). Breastfeeding is therefore best avoided in the mother who takes lithium ([Menon 2008](#)).

Drugs of misuse

The prevalence of illegal drug use in pregnancy is unknown, but one-third of drug users in the UK are female and 90% are of child-bearing age.

Effects of drug use on the mother

Drug dependency has health implications for the mother as regards nutritional, medical and sociopsychological aspects. In cases of intravenous drug use, there are greater risks of infectious diseases such as human immunodeficiency virus, hepatitis, abscesses and

endocarditis that may account for the prematurity, low birthweight and poor nutritional status observed in the offspring of these women (Fischer 2000).

Opioids

Dependence on heroin is associated with low birthweight, prematurity and fetal demise (Hulse et al. 1997). Clinical signs of neonatal abstinence include: gastrointestinal disturbances, irritability, hyperactivity, feeding and sleeping disturbances, autonomic hyperactivity and, rarely, seizures (Osborn et al. 2004). The onset, duration and severity of neonatal symptoms vary, but usually start within 24–72 hours of delivery.

Cocaine and amphetamines

Cocaine can be injected, snorted or inhaled. It is a potent vasoconstrictor and can reduce maternofetal blood flow and cause maternal hypertension. Fetal complications associated with cocaine use during pregnancy include placental abruption, intrauterine growth restriction, congenital anomalies affecting the ocular and urogenital systems and spontaneous abortion. The mother may develop pre-eclampsia, pulmonary oedema, seizures and cardiac arrhythmias (Bandstra and Burkett 1991).

How are pharmacological agents handled in pregnancy and breastfeeding?

Pharmacokinetic and pharmacodynamic changes during pregnancy have an impact on maternal drug levels and efficacy. These changes include delayed gastric emptying, increased plasma volume, decreased albumin levels (decreased drug–protein binding), enhanced hepatic metabolism and increased renal clearance. The speed of drug elimination, the lipid solubility of the drug and whether it is protein-bound will have an effect on how much passes across the placenta.

The placenta

The placenta may be a mechanical barrier which blocks the passage of large molecules between mother and fetus, but most drugs eventually pass across this lipid membrane by passive diffusion. Drugs which pass across the placenta most quickly are of high lipid solubility, low molecular weight and have reduced protein binding and slow elimination from the maternal circulation.

There are several other ways in which drugs pass across the placenta. These include passive diffusion, active transfer, facilitated diffusion, phagocytosis and pinocytosis. The placenta is also filled with enzymes that degrade drugs and hormones. For example, thyroxine is metabolised by type 3 iodothyronine deiodinase (D_3) and reduces uteroplacental passage of maternal thyroxine.

Timing and dosing of drug exposure during pregnancy

Possible toxic effects of drugs on the fetus are organised into five categories that relate to the timing of drug exposure during pregnancy: (1) miscarriage; (2) physical malformation; (3) growth impairment; (4) behavioural teratology; and (5) neonatal toxicity. Exposure to a teratogen in the 14 days postconception is likely to result in miscarriage. Drug exposure during days 14–35 of pregnancy will have the greatest effect on structural and neurochemical development. However, maternal drugs taken throughout pregnancy can have an impact on fetal neurodevelopment that only becomes evident when behavioural problems develop in childhood. Maternal medicines taken near delivery can have a directly toxic effect on the neonate, for example benzodiazepines at term occasionally cause transient sedation of the neonate and then withdrawal symptoms.

The fetus is predisposed to damage from pharmacological agents owing to low levels of drug-binding plasma proteins, immature hepatic metabolism and a permeable blood–brain barrier. Furthermore, transportation of drug metabolites back to the maternal circulation often leads to higher drug concentrations in fetal than in maternal blood (Table 11.1).

Table 11.1 US Food and Drug Administration categories for drug use in pregnancy

CATEGORY	INTERPRETATION
A	Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities to the fetus in any trimester of pregnancy
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well-controlled studies in pregnant women or: Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester
C	Animal studies have shown an adverse effect and there are no adequate and well-controlled studies in pregnant women or No animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women
D	Adequate well-controlled or observational studies in pregnant women have demonstrated a risk to the fetus; however, the benefits of therapy may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective
X	Adequate well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks The use of the product is contraindicated in women who are or may become pregnant

Pharmacotherapy during lactation

Apart from improved mother–child bonding, breastfed babies benefit from lower prevalence rates of infection and mortality rates and also improved later cognitive development and intellectual function (Fergusson et al. 1982; Lucas et al. 1992). Maternal benefits include facilitation of involution of the uterus and suppression of ovulation. It is therefore important that women who take medication are informed as to whether they can safely breastfeed whilst on their medication.

The passage of a drug into breast milk is influenced by many factors, including its volume of distribution, molecular weight, lipid/water solubility, relative affinity for plasma and milk proteins, the pH of blood and milk (the degree of ionisation of a drug) and blood flow to the breast. Once a drug is absorbed into the bloodstream, a proportion binds to plasma proteins. The remaining unbound (free, active) drug is able to cross membranes and enter breast milk. Lower molecular weight and higher lipid solubility facilitate passage of drugs into breast milk. The absolute dosage of drug received by a breastfed infant is also affected by milk yield, milk composition, and the degree of breast emptying during a previous feed. Breast milk has a lower pH than plasma, so the pH of the drug is important in the way it may be handled by diffusion

into the alveolar ducts of the breast. Hind milk (the milk that is expressed towards the end of a feed) carries a high concentration of lipids and therefore a greater concentration of lipid-soluble drugs. In contrast, colostrum exhibits a high protein level and therefore a high concentration of protein-bound drugs.

It is prudent to monitor breastfed babies for signs of drug-related toxicity and adverse effects. The physiology of the neonate (more so the preterm baby) is immature and characterised by a limited ability to metabolise and excrete drugs. Hepatic function (oxidation and glucuronidation) is immature. Renal function too is immature, characterised by lower glomerular filtration and tubular secretion rates, with resultant higher plasma drug concentrations. Gastric pH is higher and bowel motility slower, with consequent unpredictable drug absorption. Bioavailability of medications is also different: a lower degree of plasma protein binding relative to the adult implies higher free (active) drug levels. The capacity to metabolise drugs however increases rapidly, and by the third month of life often exceeds that of the adult. The factors affecting infant exposure to drugs are therefore highly variable. Maternal drug dosages consistent with the absence of ill effects on the breastfed baby remain to be established, although an infant plasma concentration of 10% (or less) of that established as therapeutic in the mother is considered acceptable and safe (Bennett 1996).

Introduction

There is increasing evidence that safe high-quality maternity services are best provided by multidisciplinary teams led by fully trained obstetricians and midwives working with neonatologists, anaesthetists and many other specialist care providers. *Safer Childbirth* (Royal College of Obstetricians and Gynaecologists (RCOG) 2007) and *Standards for Maternity Care* (RCOG 2010) have set the standards by which this care may be best achieved. The aim of modern obstetric management is the early identification of complicated pregnancies and those with abnormal placental function (National Institute for Health and Clinical Excellence (NICE) 2010), so that medical care may be focused on those women. Women with low-risk pregnancies should have their care provided by midwives (NICE 2010).

The aim of this chapter is to outline the intrapartum assessment of the fetus who is thought to be normal. Antenatal assessment of fetal well-being is also very important and is covered in detail in other chapters of this book.

Common complications that occur in labour and the management strategies will be covered in this chapter. Clearly, this account cannot be exhaustive: the intention is to concentrate on aspects of obstetric care of relevance to the neonatologist. Further reading and useful weblinks are included at the end of the chapter.

Intrapartum assessment and management

This section begins by discussing the mechanism of normal labour and the use of Syntocinon to correct slow progress in labour. Fetal response to labour and ways of assessing intrapartum fetal well-being are discussed, as are the different modes of delivery and why any particular way is chosen.

Diagnosis of labour

Recognition of the onset of labour determines all subsequent management objectives. The onset of labour is a complex physiological process and cannot easily be defined by a single event. Although labour is a continuous process, it is convenient to divide it into stages in order to ensure that the woman and the staff providing her care have an accurate and shared understanding of the concepts, enabling them to communicate effectively.

Latent first stage of labour

The onset of labour is a transition period from 'not in labour' to the diagnosis of active labour; this period is called the latent phase. In a woman having her first baby this period of time can last for several days, whereas in a multiparous patient it frequently does not occur at all. During this time there are painful contractions, with gradual cervical change, including effacement (shortening) of the cervix and dilatation up to 3–4 cm. During this period women are encouraged to stay at home, mobilise and not to focus on the contractions.

Established first stage of labour

The diagnosis of labour is made when there is progressive cervical dilatation in the presence of regular painful contractions and descent of the presenting part.

Once labour has been established, regular examinations of the cervix are performed (NICE guidelines (NICE 2010) on intrapartum care suggest 4-hourly), and the rate of cervical dilatation is plotted against time on a graph described as a partogram. The average rate of cervical dilatation and the construction of a partogram against which progress could be charted were established by studying a very large number of women in normal labour (Philpott 1972); women falling behind the average rate of progress, determined as a rate of cervical dilatation at 1 cm per hour, are readily identified by charting their progress on the partogram, and following medical review they can be considered for augmentation of labour with Syntocinon.

This charting of labour progress led to 'active management of labour' (O'Driscoll et al. 1984; Sadler et al. 2000; Tabowei and Oboro 2003), whereby women falling outside 'normal' progress automatically had augmentation of labour. It is now clear, however, that the active management of labour does not reduce the rate of caesarean section (CS) or increase spontaneous vaginal birth. In addition the injudicious use of Syntocinon in the presence of fetal compromise has considerably worsened the condition of many babies at birth. It is clear that regular training and updating of midwifery and medical staff are mandatory in units where Syntocinon is routinely used to ensure that the hypoxic fetus is recognised early and timely intervention undertaken to protect the baby.

Second stage of labour

Once the cervix is fully dilated (second stage), progress is defined as descent of the presenting part through the birth canal. This is judged by hourly vaginal examinations. In the absence of an epidural, the usual limits of duration for pushing are 60–90 minutes for a woman having her first baby and 30–60 minutes for multiparous women. These recommendations have some support, in that fetal hypoxia and acidaemia increase progressively during the second stage (Humphrey et al. 1974; Aldrich et al. 1995; Honjo and Yamaguchi 2001; Nordstrom et al. 2001). However, in recent years, with the increasing use of epidural analgesia (Caliskan et al. 2010), allowing more time in the second stage before starting active pushing has been shown to improve the chance of vaginal delivery (Hoult et al. 1977; Hansen et al. 2002) without a major deterioration in fetal pH. Nevertheless, the need for operative assistance in the presence of an epidural remains significantly increased (Fraser et al. 2000), and many consider one additional hour sufficient to minimise this possibility (Maresh 1983). NICE recommends that in nulliparous women birth should be expected to occur within 3 hours of the start of the active second stage (NICE 2010). A diagnosis of delay in the active second stage should be made after 2 hours of active pushing in a primiparous and 1 hour in a multiparous woman. Unless delivery is imminent the usual action would be to ask for a medical review to assess the condition of both the mother and her baby and to determine whether an operative vaginal birth is required.

Interventions during labour

Amniotomy and augmentation of labour with an intravenous infusion of Syntocinon are interventions that are regularly undertaken when labour progress is deemed to be slow.

Amniotomy

Active management of labour includes routine amniotomy (membrane rupture) if the cervix fails to dilate 2 hours following the diagnosis of labour (O'Driscoll et al. 1984; Frigoletto et al. 1995; Rogers et al. 1997). While there is some evidence (Smyth 2007) that there may be a reduction in the length of the second stage of labour in women having their first baby, earlier amniotomy is associated with a higher incidence of caput formation and moulding of the fetal head (Caldeyro-Barcia 1974) and an increased incidence of early uniform fetal heart rate (FHR) decelerations and a significantly lower median umbilical artery pH at birth (albeit still within the normal range) (Caldeyro-Barcia 1974). These findings can be explained on the basis of increased uterine activity, greater head compression and (probably most importantly) cord compression. In the presence of an abnormal FHR pattern membrane rupture may provide additional information if meconium is present, although 20% of normal women will have meconium present in the amniotic fluid (Gibb 1992). Rupture of the membranes is also required before fetal blood sampling (FBS) or application of a fetal scalp electrode.

Meconium

The incidence of meconium in the liquor increases with advancing gestational age (Oyelese 2006). The overall reported incidence is 12%, with an incidence of less than 10% at 38 weeks to virtually 100% of pregnancies at 42 weeks complicated by meconium staining of the liquor. The prelabour passage of meconium may reflect

Table 12.1 National Institute for Health and Clinical Excellence categorisation of fetal heart rate features

FEATURE	BASELINE (bpm)	VARIABILITY (bpm)	DECELERATIONS	ACCELERATIONS
Reassuring	110–160	≥5	None	Present
Non-reassuring	100–109	<5	Typical variable decelerations with over 50% of contractions, occurring for over 90 minutes. Single prolonged deceleration for up to 3 minutes	The absence of accelerations with otherwise normal trace is of uncertain significance
Abnormal	<100 >180 Sinusoidal pattern ≥10 minutes	<5 for 90 minutes	Either atypical variable decelerations with over 50% of contractions or late decelerations, both for over 30 minutes. Single prolonged deceleration for more than 3 minutes	

a previous transient fetal stimulation, possibly hypoxia, and infection and thyrotoxicosis are rare causes. The passage of meconium in utero is associated with significant increases in perinatal morbidity and mortality (Nathan et al. 1994; Martin and Vidyasagar 2008) as the aspiration of meconium into the lungs during intrauterine gasping, or when the baby takes its first breath, can result in a life-threatening disorder known as meconium aspiration syndrome (Maresh 1983).

Occasionally green 'meconium-stained' liquor is actually bile-stained, due to fetal vomiting associated with intestinal obstruction. Thus, meconium remains an indication for continuous electronic FHR monitoring (EFM) during labour, and the presence of meconium lowers the threshold for making a diagnosis of fetal hypoxia if FHR abnormalities occur.

Effects of oxytocin

The aim of augmentation of labour with Syntocinon infusion is to achieve optimal uterine activity with a maximum contraction frequency of 4–5/10 minutes. Uterine perfusion decreases during contractions as a result of a decrease in blood flow to the intervillous space (Peebles et al. 1994; Simpson 2004). Fetal oxygenation remains unaffected, as long as there is sufficient time for relaxation between contractions to allow reperfusion of the placental bed (Simpson and James 2008). Nevertheless, in clinical practice the use of Syntocinon is associated with an increased incidence of FHR decelerations and therefore vigilance is essential, and requires continuous high-quality recording of the FHR (Bakker et al. 2007).

Electronic fetal heart rate monitoring

Several randomised controlled trials have suggested that continuous EFM confers no advantage over intermittent auscultation for normal, uncomplicated labours (MacDonald et al. 1985; Thacker 2004). When continuous monitoring is indicated the cardiotocogram (CTG) must be interpreted in the context of the clinical picture.

Recently produced evidence-based guidelines on the use and interpretation of the CTG in intrapartum fetal surveillance have been produced (NICE 2010). This guideline categorises FHR features into

Table 12.2 National Institute for Health and Clinical Excellence categorisation of fetal heart rate (FHR) traces

CATEGORY	DEFINITION
Normal	An FHR trace in which all four features are classified as reassuring
Suspicious	An FHR trace with one feature classified as non-reassuring and the remaining features classified as reassuring
Pathological	An FHR trace with two or more features classified as non-reassuring or one or more abnormal categories

'reassuring', 'non-reassuring' and 'abnormal' groups (Table 12.1), enabling classification of the CTG trace as 'normal', 'suspicious' or 'pathological' (two non-reassuring features, or one abnormal feature) (Table 12.2). 'Suspicious' traces can be managed conservatively but 'pathological' traces demand either a FBS or delivery.

Baseline rate

This is the mean FHR in beats per minute (bpm) determined over a 5–10-minute interval, when stable in the absence of accelerations and decelerations. The normal baseline FHR lies between 110 and 160 bpm at term (Table 12.1).

Fetal tachycardia

Acute rises in FHR in labour may reflect an increase in catecholamine secretion and indicate an early adaptive response to fetal hypoxia before the development of fetal acidemia. Chorioamnionitis should always be suspected. Epidural analgesia can cause maternal fever and fetal tachycardia (Macaulay et al. 1992). Rarely a fetal tachyarrhythmia may be recognised for the first time in labour. Fetal tachycardia above 180 bpm has traditionally been regarded as a sign of fetal compromise, particularly if found in association with other abnormal FHR patterns when the likelihood of acidosis is significantly increased (Fig. 12.1). FBS or delivery then becomes a priority.

Fig. 12.1 Baseline tachycardia.

Fetal bradycardia

A persistent low baseline between 100 and 110 bpm can be seen in some postdate pregnancies and in fetuses whose mothers are taking drugs such as beta-blockers. Fetal heart block is another possibility.

Acute bradycardia below 100 bpm can occur following vaginal examination and full dilatation of the cervix and after epidural top-ups. An acute fall in FHR indicates an acute interruption of oxygen delivery, secondary to maternal hypotension/aortocaval compression, umbilical cord compression, cord prolapse, placental abruption or, rarely, a ruptured uterus (Fig. 12.2). Acidemia develops within 10–15 minutes and will continue to progress unless the situation is corrected. If the bradycardia fails to recover after appropriate treatment, immediate delivery is necessary (Verspyck and Sentilhes 2008). However, if the baseline FHR returns to normal and there are no other abnormal FHR features, conservative management is appropriate. Fetal bradycardia in association with other FHR abnormalities described has been progressive bradycardia associated with absent FHR variability, which is regarded as a terminal response of a dying fetus (Verspyck and Sentilhes 2008) (Fig. 12.2).

Baseline variability

This refers to oscillations of the recorded baseline FHR. During periods of fetal activity, baseline variability is usually ≥ 5 bpm (< 25 bpm) and there should be two or more accelerations in a 20-minute period (Fig. 12.3). Episodes of low variability, often less than 5 bpm, are associated with the quiet fetal behavioural state (Beard et al. 1971). Such physiological episodes do not last more

than 40 minutes. Excessive variability (> 25 bpm) is an early adaptive response to fetal hypoxia, and in isolation is not found to be predictive of fetal acidemia. Commonly, however, abnormalities of the baseline variability are seen in conjunction with other FHR abnormalities. In such cases further tests of fetal well-being are appropriate.

Accelerations

An acceleration is a transient rise in FHR of at least 15 bpm, which lasts for more than 15 seconds. If the rate remains raised then this may be considered tachycardia. It has been known for some time that acceleration is the only pattern not related to fetal acidemia (Trochez et al. 2005).

Decelerations

A deceleration is a transient fall in FHR. Decelerations are not part of the normal CTG appearance in term fetuses. In general, decelerations should be considered transient bradycardias. Fetal acidemia only occurs after a considerable reduction in fetal oxygen delivery.

Early decelerations

These are decelerations in which the trough of the decrease in the FHR is synchronous with the peak of the uterine contraction and does not fall below 90 bpm. They are rare, occur when the head is deeply engaged in the late first stage or early second stage and are generally benign. If the early decelerations persist in the presence of a delayed second stage or there are other abnormalities of the FHR, FBS or delivery is indicated.

Fig. 12.2 Prolonged deceleration.

Fig. 12.3 Normal CTG.

Variable decelerations

A variable deceleration ([Kazandi et al. 2003](#)) is one where the morphology of the deceleration and/or the timing in relationship to the contraction varies ([Figs 12.4 and 12.5](#)). Typical variable decelerations are a fetal response to cord compression where the fetus is coping with labour; [NICE guidance \(2010\)](#) suggests that

they only become a non-reassuring feature if they are present for greater than 50% of contraction over a 90-minute period. Atypical variable decelerations are an abnormal feature on a CTG and suggest fetal acidosis; if they occur for greater than 50% of contractions over a 30-minute period then either FBS or delivery is mandatory.

Fig. 12.4 Variable decelerations.

Late decelerations

These are decelerations in which the trough of the decrease in the FHR occurs after the peak of the uterine contraction. They are associated with fetal acidemia and when present the fetus must either have further assessment by FBS or be delivered within 30 minutes. Late decelerations, particularly in the setting of other FHR abnormalities, suggest fetal hypoxia secondary to uteroplacental insufficiency. The characteristic changes associated with chronic placental failure include loss of accelerations, reduced baseline variability and the onset of recurrent decelerations (Fig. 12.4).

Preterm fetus

The interpretation of the FHR pattern of the preterm fetus in labour is similar to that of its term counterpart, with some subtle differences. The baseline is higher and the variability is often less. Accelerations occur less frequently and are less marked. The differentiation between quiet and active sleep patterns may not be evident until 32 weeks' gestation. Small brief (20-second) decelerations are often seen and are not considered significant.

Sinusoidal and pseudosinusoidal fetal heart rate patterns

The classical CTG pattern in severe fetal anaemia is described as 'sinusoidal' (Fig. 12.6). This is a preterminal pattern which is rarely seen. Five rigid criteria must be fulfilled to make the diagnosis (Modanlou and Murata 2004):

1. a stable baseline FHR of 120–160 bpm, with regular oscillations
2. an amplitude of 5–15 bpm
3. a frequency of 2–5 cycles/min
4. absent short-term variability
5. no areas of normal FHR variability or reactivity.

Pseudosinusoidal fetal heart rate patterns

Pseudosinusoidal FHR patterns (vaguely defined as undulatory waveforms), in contrast, are common and usually benign. They are strongly associated with the use of pethidine and epidural analgesia and are also seen with fetal sucking movements. Such patterns will generally improve with time.

From the review of FHR patterns it is clear that no single abnormal pattern reliably predicts fetal outcome. Comprehensive evaluation of all the FHR characteristics must be integrated into the clinical scenario before decisions can be made on management. Of most importance is the influence of prelabour placental insufficiency on fetal tolerance to interruptions in oxygen delivery during labour. Acidemia develops more rapidly in cases of intrauterine growth restriction (Verspyck and Sentilhes 2008).

The future of FHR monitoring requires further understanding and acceptance of the need for a more physiological approach to interpretation (Verspyck and Sentilhes 2008).

Fetal scalp blood sampling

Clinical trials have shown that there is an increased risk of CS if CTG is used without FBS. This has led NICE to recommend that EFM should not be used without facilities for FBS (RCOG 2001). Fetal scalp sampling involves taking a small sample of blood from the fetal scalp. It is a difficult process for both the mother and the doctor as it is uncomfortable and can be technically difficult to perform, particularly if the cervix is less than 4 cm dilated. The mother is positioned in the left lateral position and an amnioscope (a specially designed speculum) is inserted into the vagina. Under direct vision the skin of the fetal scalp is punctured and a capillary tube of fetal blood is collected and then analysed in a blood gas analyser.

The normal values for pH in fetal scalp blood are shown in Table 12.3. If the pH is 7.2 or less, immediate delivery is indicated. If the

UA P_{CO_2} (mmHg)	53	10	35
UA P_{O_2} (mmHg)	17	6	6
UA BE (mEq/l)	24	3	211
UV pH	7.34	0.06	7.20
UV P_{CO_2} (mmHg)	41	7	28
UV P_{O_2} (mmHg)	29	7	16
UV BE (mEq/l)	23	3	28

UA, umbilical artery; BE, base excess; UV, umbilical vein.

pH is greater than 7.2, it is appropriate to continue with the labour and repeat the test, unless the situation deteriorates, necessitating earlier intervention. The rate of fall of the fetal scalp pH is as important as each absolute value. This must be integrated into the clinical picture.

Fetal pH falls more rapidly during active second stage (Hofmeyr 2004). Data from normal labours suggest that the scalp pH decreases by 0.016 pH units per hour in the first stage of labour and by 0.11 pH units during the second stage of labour. The rate of fall in the second stage of labour may be higher during a prolonged bradycardia with a rate of fall as high as 0.1 units per 10 minutes, and rapid delivery is essential to prevent acidemia at birth (Sheiner et al. 2001).

Umbilical cord blood sampling

Measurement of pH and blood gas values from umbilical cord blood immediately after delivery is an invaluable guide to the condition of the fetus at birth. Umbilical venous blood values give an indication of the effects of placental gas transfer and correction of buffered arterial metabolic acids. Oxygen saturation and pH values are always higher in umbilical venous blood, which is the best representation of cerebral blood oxygen content. Umbilical arterial blood gas analysis indicates the fetal response to labour and reflects the situation in the blood supplying the lower fetal body (Spencer 1993).

The normal values for umbilical blood gas results are shown in Table 12.4. Arterial and venous cord pH are likely to be significantly different if there is an element of cord compression, hence the

importance of taking paired cord blood samples (Westgate et al. 1994). The normal range defines the 'physiological acidemia' of the normal, vigorous newborn. Indeed, umbilical artery pH values above 7.05 in term infants show no significant association with low Apgar scores or adverse neurodevelopmental outcome (Goldaber et al. 1991). Correction of even quite marked acidemia after birth by healthy babies is rapid and correlates with a low P_{aCO_2} at 1 hour of age.

The distribution of umbilical arterial pH values in preterm infants (<32 weeks) is skewed to the left, with lower values. The median value was pH 7.25, but the range was wide (Zanini et al. 1980). There is an association between umbilical arterial pH values below pH 7.0 and adverse outcome in the preterm baby (Victory et al. 2003).

Delivery of the baby

This section covers mode of delivery, including common indications for specific modes of delivery. The indications for CS, instrumental delivery and induction of labour in term infants will be outlined, with particular reference to possible fetal complications. The management of breech presentations and multiple pregnancies will be discussed separately.

Term infants

The majority of term infants will deliver normally, with or without assistance. In the UK the aim is to provide all women with 1:1 care in labour (RCOG 2007) and, in addition, some women will choose to have a doula with them to provide additional support. While UK operative vaginal delivery rates have remained constant at approximately 11%, CS rates are increasing. The CS rate in England and Wales was 21.5% in 2000/01 compared with 10.4% in 1985. The drive to reduce the CS rate includes encouraging vaginal birth after caesarean (VBAC) birth, and refusing to perform CS for maternal request. The concern about the rising CS rate is the increased rate of complications in subsequent pregnancies. There is a higher rate of scar pregnancies and abnormal placentation in women with a previous CS (Rosenberg et al. 2010) as well as convincing epidemiological data showing an increase in stillbirth in a subsequent pregnancy (Smith et al. 2003).

Caesarean section

In the recent national audit (Thomas 2001), 37% of the CSs performed in England and Wales were planned. The most frequent indications were previous CS and breech presentation (Thomas 2001). There are a few 'absolute' indications for elective CS, for instance major placenta praevia or abnormal lie, where the baby cannot be safely delivered vaginally (Hannah et al. 2000). In maternal HIV infection with a high viral load there is evidence that CS delivery offers a considerable degree of protection for the baby from vertical transmission (Newell 2000).

It is widely assumed that elective CS ensures good condition at birth, and certainly the incidence of neonatal seizures and encephalopathy in babies born by elective CS is very low. However, maternal hypotension due to regional anaesthesia, with or without aortocaval compression, can reduce placental perfusion and lead to acute fetal hypoxia. There is an increased incidence of fetal respiratory complications, such as transient tachypnoea of the newborn and hyaline membrane disease in the absence of the normal 'stress' of labour (Morrison et al. 1995). The risk of neonatal respiratory morbidity is related to the gestational age at which the elective CS is

performed. For this reason, an elective CS should usually be undertaken at or after 39 weeks of gestation.

Emergency CS may be indicated either for fetal hypoxia or for failure to progress in labour. The urgency of the procedure will be determined by the presumed aetiology and severity of the problem. Rather than attempting vaginal delivery the data suggest that, in cases of placental abruption with evidence of fetal compromise, perinatal outcome is significantly improved by urgent CS (Okonofua and Olatunbosun 1985; Green 1989).

Instrumental vaginal delivery

This is usually indicated for fetal compromise, delay in the second stage of labour or maternal exhaustion. Instrumental vaginal delivery can be performed using either forceps or the ventouse and both of these can cause significant complications to the mother and fetus (Ezenagu et al. 1999; Gardella et al. 2001; Al-Kadri et al. 2003).

Neonatal intracranial and subgaleal haemorrhage are potentially life-threatening complications (Whitby et al. 2004). In one review the rate of subdural or cerebral haemorrhage in ventouse deliveries did not differ significantly from that associated with forceps use or CS during labour (Whitby et al. 2004). There is a clear link between the use of the ventouse and subgaleal haemorrhage, with an incidence of around 1 in 1000 normal deliveries compared with 7 per 1000 ventouse births (Towner et al. 1999).

The risk of extracranial or intracranial trauma relates to the cup application time, number of pulls, and whether or not two sets of instruments are used (Gardella et al. 2001). The risk is further increased when delivery is completed by CS following a protracted attempt at operative vaginal delivery (Ezenagu et al. 1999). CS in the second stage of labour is associated with an increased risk of major obstetric haemorrhage, prolonged hospital stay and admission of the baby to the special care baby unit compared with completed instrumental delivery.

Rotational delivery with the Kielland forceps carries additional risks and requires specific expertise and training, which is becoming scarce (Chow et al. 1987). Alternatives to rotational forceps include manual rotation followed by direct traction forceps or rotational vacuum extractor.

Shoulder dystocia

Shoulder dystocia is defined as a delivery where additional obstetric manoeuvres are required to deliver the shoulders of the baby, it occurs when the anterior shoulder impacts against the maternal symphysis or rarely the posterior shoulder against the sacral promontory. It is an obstetric emergency as delay in delivering the baby will lead to rapid hypoxia and death unless delivery is effected rapidly. The Confidential Enquiry into Stillbirths and Deaths in Infancy report noted that 47% of babies who die after a shoulder dystocia did so within 5 minutes of the head being delivered (Focus Group Shoulder Dystocia 1998). Shoulder dystocia has a reported incidence of 0.6% and is associated with a high perinatal morbidity and mortality; there are also maternal complications with a high incidence of fourth-degree tears and postpartum haemorrhage. The principal risk factor is fetal macrosomia, although the majority of cases occur in infants weighing <4500 g (Focus Group Shoulder Dystocia 1998; RCOG 2005). Additional risk factors include maternal diabetes mellitus, a history of previous shoulder dystocia, prolonged labour and delay in the second stage of labour. Obstetric brachial plexus injury complicates about 4–16% of all cases of shoulder dystocia, of which 10% of the babies will have permanent damage, usually an Erb's palsy ($p > 0.000$). Unfortunately, at present

there is no reliable method for antenatal prediction of shoulder dystocia.

A number of manoeuvres can be employed to expedite delivery of the shoulders and all obstetricians and midwives should have regular training in 'shoulder dystocia drills' (Focus Group Shoulder Dystocia 1998; RCOG 2005). Rarely, deliberate fracture of the baby's clavicles is necessary.

Induction of labour

Most women will go into labour before 42 weeks. Induction of labour is generally offered between 41 and 42 weeks, to reduce the risks of postmaturity, and prolonged pregnancy is the commonest indication for induction of labour. A policy of offering routine induction of labour after 41 weeks reduces perinatal mortality without increasing the CS rate (Okonofua and Olatunbosun 1985). The insertion of vaginal prostaglandin E₂ is the preferred method of induction unless the cervix is already shortened (effaced) and starting to dilate, when artificial membrane rupture and Syntocinon stimulation should be used. Hyperstimulation is a potential complication inherent to all these methods and causes inappropriate myometrial reaction. Hyperstimulation can result in hypertonus or tachysystole (>6 contractions in 10 min). In either case, the fetus does not have long enough to recover from the acute hypoxic stress of the uterine activity and CTG abnormalities ensue. Women with prelabour rupture of the membranes at term may also require induction of labour if they do not go into labour. This group of women should be offered either conservative management or immediate stimulation of labour. If the woman chooses to wait she will normally be readmitted 24 hours after the membrane rupture. As prolonged rupture of the membranes of >18 hours is associated with an increased risk of infection with group B *Streptococcus*, women in this group should be offered intravenous antibiotics (Shipp et al. 1999).

Breech presentation

The management of term breech presentations has, until recently, been the subject of intense controversy. The interpretation of studies that compare outcome after vaginal breech birth and cephalic birth is confounded by the fact that breech presentation per se appears to be a marker for poor perinatal outcome. Thus, poor outcomes following vaginal breech birth may be the result of underlying conditions causing breech presentation rather than damage during delivery. However, the care during labour, the delivery methods used and the skill of the birth attendant may also influence outcome.

Vaginal breech delivery carries the risk of cord compression/prolapse, extended arms at delivery and difficult delivery of the aftercoming head. This risk may be approximately 1–2%. The controversy over the mode of delivery of term breech presentations was finally clarified with the publication of the Term Breech Trial (Hannah et al. 2000). This was a randomised controlled trial to compare a policy of planned CS with planned vaginal birth for selected breech presentation pregnancies. The three primary outcomes – perinatal mortality, neonatal mortality and serious neonatal morbidity – were significantly lower for the planned CS group than for the planned vaginal birth group, with no differences in serious maternal complications. Consequently, most clinicians in the UK now recommend elective CS for term breech singletons. Some vaginal breech deliveries will inevitably occur, for instance in undiagnosed breeches in the second stage of labour, or as a result of informed maternal choice. In such an event an experienced obstetrician or midwife should conduct delivery. Continuous EFM should

be instituted and early CS should be performed, particularly in the event of poor progress in the second stage of labour.

The challenge for clinicians now is how to maintain and teach vaginal breech delivery skills when these deliveries occur so infrequently.

The alternative management for the breech presentation at term is to offer external cephalic version (ECV). ECV at term can reduce non-cephalic births by nearly 60% (Hofmeyr 2000) and routine tocolysis appears to be effective (Hofmeyr 2004). ECV does carry small risks of fetal bradycardia and fetomaternal haemorrhage and therefore should be performed on the labour ward with access to obstetric theatre.

Multiple pregnancy

The optimal mode of delivery in multiple pregnancies is controversial. Elective CS is frequently performed for triplets and higher order multiples, although no randomised controlled trials are available to support this practice. The planned mode of delivery of twins will be influenced by both the chorionicity and the presentations. In dichorionic diamniotic twin pregnancy with a vertex–vertex presentation, most obstetricians would currently advise vaginal delivery (Chervenak et al. 1985). When the first twin presents as a breech, delivery by CS is often recommended (Chervenak et al. 1985), based on findings from the Term Breech Trial in singletons (Hofmeyr 2000). For twins presenting as first twin vertex, second twin non-vertex, opinion is divided as to the optimal mode of delivery. Some would perform an elective CS, believing that this reduces the neonatal mortality and morbidity of the second twin (Smith et al. 2002). It has been suggested that second twins born at term are at substantially higher risk of death than first twins owing to complications of vaginal delivery (Smith et al. 2002) irrespective of the presentation of the second twin. Others would advocate that, with careful fetal monitoring and recourse to urgent CS if necessary, the risks to the second twin can be minimised. Vaginal delivery of the second, non-vertex, twin can be effected by internal podalic version followed by breech extraction.

In an attempt to clarify the situation, the group that carried out the Term Breech Trial is currently setting up the Term Twin Trial. Hopefully it will provide a definitive answer to the optimal mode of delivery of term twins.

The situation with monochorionic twins is not as clear: approximately 33% of all twins are monochorionic, i.e. they share the same placenta and vascular placental anastomoses. Complications include twin–twin transfusion syndrome, the complications that arise with the death of a co-twin and discordant malformation. Chorionicity can be reliably determined at the 12-week scan and regular ultrasound scans are the mainstay of antenatal management. The perinatal mortality rate for monochorionic twins is quoted as 11% compared with 5% in dichorionic twins and the increased risk continues after 32 weeks (Duncan 2005). The recommendations are that monochorionic twins should be delivered at 36–37 weeks. There is no clear evidence about mode of delivery, although the quoted incidence of 10% for acute twin-to-twin transfusion syndrome has led to many obstetricians delivering all monochorionic twins by planned CS (Barigye et al. 2005).

Other high-risk situations for the fetus

Cord prolapse

Cord prolapse has been defined as the descent of the umbilical cord through the cervix alongside (occult) or past the presenting part

(overt) in the presence of ruptured membranes (Beard and Johnson 1972). The overall incidence of cord prolapse ranges from 0.1% to 0.6% (Macaulay et al. 1992) and is higher in breech presentation, at ~1% (Lin 2006).

The principal cause of asphyxia is cord compression and umbilical arterial vasospasm. Manual elevation is achieved by inserting a gloved hand in the vagina to displace the presenting part upwards. If the delivery is likely to be prolonged, particularly if it involves ambulance transfer, elevation through bladder filling (Foley catheter with 500–750 ml of normal saline and clamped) may be more practical. Tocolysis has been used to reduce contractions and correct bradycardia (Draycott 2008).

CS is associated with a lower perinatal mortality than spontaneous vaginal delivery in cases of cord prolapse when delivery is not imminent. However, when vaginal birth is imminent, outcomes are similar to or better than CS. The prognosis of cord prolapse managed in a hospital setting is generally good; most units will regularly run drills to practise for unexpected cord prolapse (Murphy and MacKenzie 1995).

Ruptured uterus

Ruptured uterus is another obstetric emergency in which fetal compromise can rapidly develop. It typically occurs in multiparous women with a uterine scar or with uterine stimulation with Syntocinon. The classical clinical symptoms and signs are severe pain (which will 'break through' epidural analgesia), cessation of contractions, intrapartum bleeding and haematuria. Early warning signs are often seen on the CTG. The fetal outcome from this acute hypoxic insult will be determined by the speed of delivery and the fetal condition prior to uterine rupture. The prognosis for babies delivered from the maternal peritoneal cavity, having been completely extruded from the uterus, is poor (Leung et al. 1993).

Maternal cardiac/respiratory arrest

Finally, in the rare event of maternal cardiac/respiratory arrest, fetal delivery is often essential if maternal resuscitation is to succeed. The physical effects of a third-trimester uterus on lung expansion and aortocaval compression make maternal resuscitation difficult. If the maternal condition is not dramatically improved after 5 minutes of intensive resuscitation, rapid fetal delivery by CS should be performed. Both the maternal and fetal outcomes are often poor. The potential causes for a maternal cardiorespiratory arrest can be amniotic fluid embolism, pulmonary embolism, myocardial infarction, massive cerebrovascular event and hypovolaemia.

Preterm infants

Preterm is defined as less than 37 completed weeks of gestation. The mode of delivery of preterm infants will be influenced by the gestational age, the fetal and maternal condition and whether the mother is already in spontaneous preterm labour. It is therefore difficult to make generalisations, and decisions need to be taken on an individual basis after discussion with the parents.

The optimal management of preterm breech presentations and multiple pregnancies is less well established than in the term setting. Unfortunately, the incidence of breech presentation is higher preterm. In the absence of good evidence that a preterm breech needs to be delivered by CS, the decision about the mode of delivery should be made after close consultation with the parents.

Multiple pregnancies are at increased risk of almost every pregnancy complication, including preterm labour and delivery.

The antenatal diagnosis of chronic uteroplacental insufficiency and its importance are discussed in detail in [Chapter 9](#). If the fetus shows sign of compromise antenatally delivery should be undertaken by CS as such fetuses are less likely to compensate for the acute hypoxic stress of reduced placental perfusion with each uterine contraction for prolonged periods. In the absence of fetal compromise, expectant management with increased fetal surveillance is preferable to delivery, as the risks of prematurity are appreciable. Rapid deterioration or abnormal CTTs should prompt delivery by CS.

Severe early-onset maternal pre-eclampsia often causes chronic uteroplacental insufficiency. Recurrent episodes of minor antepartum haemorrhage due to placenta praevia can lead to intrauterine growth restriction. The main risk to the neonate, however, is from preterm delivery. Preterm placental abruption requiring delivery is also associated with growth restriction in a substantial proportion of cases. The fetal effects of a placental abruption depend on the degree of placental separation and the condition of the placenta prior to the acute event. In addition, the maternal condition in any of these situations can be the principal indication for preterm delivery, even when the fetus appears healthy.

The optimal mode of delivery for women thought to be in labour and at high risk of delivering a small baby is controversial and there is no clear evidence to guide the obstetrician. Decisions are made on a case-by-case basis and are based on the stage of the labour, the likely outcome for the baby as well as the wishes of the parents. Before 28 weeks it can be very difficult to deliver a baby through a transverse incision as the lower segment does not form until 28 weeks, so the myometrium can be very thick, making delivery very difficult and traumatic for the baby. These operations should only ever be performed by experienced obstetricians, who will make a decision at the time of the operation as to whether to make a vertical or transverse incision in the uterus. A classical CS (i.e. a vertical incision in the uterus) is associated with an increased risk of uterine rupture in the next pregnancy. There is some evidence, however, that low vertical incisions performed to deliver the very small infant may not be associated with a high risk of scar dehiscence in the next pregnancy, and there are reports of women going on to have normal births in the subsequent pregnancy ([Shipp et al. 1999](#)). Claims that elective CS reduces the chances of fetal and neonatal death and chronic morbidity have been met by counterclaims that such a policy leads to iatrogenic preterm delivery with the additional risk of serious maternal morbidity. FBS is usually avoided because of the increased risk of serious fetal trauma. For the same reason, vacuum extraction is not used below 34 weeks and forceps delivery is performed for obstetric reasons.

Preterm labour

There are numerous predisposing causes for preterm labour and often an underlying aetiology is not identifiable. Preterm prelabour rupture of the membranes (PPROM), chorioamnionitis, polyhydramnios and antepartum haemorrhage are common pathologies leading to preterm labour. The diagnosis of preterm labour can be very difficult and many obstetricians are now testing for the presence of fibronectin to help with the diagnosis. Fibronectin is a glycoprotein which is not detectable after fusion of the membranes at 22 weeks. The presence of fibronectin after 22 weeks and before 36 weeks suggests separation of the chorion from the decidua, possibly in response to chronic inflammation. The test is performed at the bedside and has a positive predictive value of 37% but a negative predictive value of 99%. Women who present with possible preterm labour who are negative for the presence of fibronectin can

be discharged home, and when fibronectin is present admitted for tocolysis and steroids ([Berghella et al. 2008](#)).

Preterm prelabour rupture of the membranes

PPROM complicates ~2% of pregnancies but is associated with 40% of preterm deliveries and can result in significant neonatal morbidity and mortality ([Carroll et al. 1996](#)). The three causes of neonatal death associated with PPRM are prematurity, sepsis and pulmonary hypoplasia. Women with intrauterine infection deliver earlier and infants born with sepsis have a mortality rate four times higher than those without sepsis ([Maxwell 1993](#)). In addition, there are maternal risks associated with chorioamnionitis ([RCOG 2002a](#)).

PPROM is diagnosed on the basis of maternal history, liquor visualisation in the vagina and ultrasound evidence of oligohydramnios. Common aetiologies for early membrane rupture include polyhydramnios, infection, maternal urinary tract infection, cervical weakness and recurrent bleeding. After diagnosis and the exclusion of infection the management thereafter is usually expectant, the mother has careful monitoring to look for signs of infection and delivery is planned for after 34 weeks, as at gestations below this the risks of prematurity are greater than those of the most common complication, chorioamnionitis ([Fox et al. 1992](#); [Merenstein and Weisman 1996](#)). If infection develops most women will go into labour, but if not then after discussion with the mother and the neonatologist, delivery will be undertaken. Cord prolapse and placental abruption can also occur ([Maxwell 1993](#)).

Chorioamnionitis can be caused by a variety of vaginal pathogens. Group B *Streptococcus* infection can result in serious neonatal morbidity and cause preterm labour. Intrapartum antibiotics are effective and decrease neonatal colonisation, sepsis and death ([Anthony et al. 1978](#); [Boyer and Gotoff 1986](#)). Transient and intermittent carriage is common ([Anthony et al. 1978](#)) and antenatal screening is a poor predictor of the intrapartum state. Bacterial vaginosis is implicated in preterm labour ([Hay et al. 1994](#)). ORACLE (Overview of the Role of Antibiotics in Curtailing Labour and Early delivery) ([Kenyon et al. 2001, 2003](#)), a large randomised controlled trial, was set up to investigate the role of antibiotics. ORACLE I ([Kenyon et al. 2001](#)) included women with PPRM and showed that maternal administration of oral erythromycin is associated with delayed delivery and decreased respiratory, cerebral and infective morbidity. Co-amoxiclav, the other study agent, is not routinely recommended as it is associated with necrotising enterocolitis. Consequently, oral erythromycin is now routinely given to women with PPRM.

ORACLE II ([Kenyon et al. 2003](#)), which included women in threatened preterm labour without evidence of PPRM, showed no evidence of benefit from prophylactic antibiotic use. Hence antibiotics should not be routinely prescribed for women in spontaneous preterm labour without evidence of clinical infection.

Tocolysis

There are situations when urgent delivery of the preterm infant is required, such as in the presence of infection or after a placental abruption; however, for the majority of women in preterm labour it is safe to use tocolytic therapy to give time to administer antenatal steroids. When tocolytic therapy is indicated, it should be continued if possible for 48 hours to try to maximise the effects of steroids. Atosiban, an oxytocin antagonist, is effective in delaying delivery for up to 7 days and is associated with fewer maternal adverse effects ([RCOG 2002b](#)).

Antenatal steroid therapy in preterm labour

The slow uptake of maternally administered corticosteroids following the original description of benefit in 1972 (Liggins and Howie 1972) remains an important lesson in perinatal medicine. Uptake increased following a review by Crowley (2000), who demonstrated that corticosteroids reduce the occurrence of hyaline membrane disease overall, and reduce the incidence of respiratory distress syndrome, intraventricular haemorrhage, necrotising enterocolitis and neonatal death. A Cochrane review indicates that antenatal corticosteroids reduce the incidence of respiratory distress syndrome, neonatal death and intraventricular haemorrhage (Crowley 1995, 2000; NIH 1995; Penney 2004). There is evidence of benefit in all major subgroups of preterm babies, irrespective of race or gender (Elimian et al. 1999). Some still question the value of steroid therapy for those cases where preterm delivery is preceded by PPROM, especially in babies weighing ≤ 1000 g (Chapman et al. 1999; Harding et al. 2001). However, Crowley's original meta-analysis showed clear benefit for the use of antenatal corticosteroids after PPROM in reducing respiratory distress syndrome (Crowley et al. 1990; Vermillion et al. 2000). An analysis of 'the number needed to treat' suggests that at >34 weeks 94 women will need to be treated to prevent one case of RDS, while at <31 weeks one case of RDS is prevented for every five women treated (Crowley 2000).

There are growing concerns that repeated antenatal doses could cause decrease in birthweight, in fetal brain, and other organ size and abnormal neuronal development (Kay et al. 2000). Within Crowley's meta-analysis, betamethasone and dexamethasone were found to be equally effective in preventing RDS (Crowley 2000). However, a large study suggested that treatment with betamethasone, but not dexamethasone, is associated with a decreased risk of cystic periventricular leukomalacia among premature infants born at 24–31 weeks of gestation (Baud et al. 1999). The RCOG Scientific Advisory Committee recommends that betamethasone is the steroid of choice to enhance lung maturation (RCOG 2002a).

The effect of treatment is optimal if the baby is delivered >24 hours and <7 days after the start of treatment (Crowley 2004).

In clinical practice, elective use of steroids is often used where preterm delivery is anticipated, for instance severe intrauterine growth restriction, severe pre-eclampsia and multiple pregnancies. The effects of steroids used for these purposes, however, have not been fully established.

Maternal diabetes mellitus is a recognised risk factor for neonatal respiratory distress syndrome (Carlson et al. 1984; Mimouni et al. 1987). The use of antenatal corticosteroids in pregnancies complicated by maternal diabetes mellitus is recommended, but a significant reduction in rates of respiratory distress syndrome has not been demonstrated.

Part 1: Stabilisation and resuscitation of the newborn

Colm O'Donnell Colin J Morley

Many interventions, including pinching, shaking and electrocution, have been used to revive apparently lifeless newborns over the years, with claims for success made for all (Fig. 13.1; O'Donnell et al. 2006a). A series of animal experiments by a group of physiologists led by Geoffrey Dawes in the 1950s and 1960s demonstrated the

importance of positive-pressure ventilation (PPV) in neonatal resuscitation (Dawes 1968). In the seminal experiment, a term rhesus monkey was delivered and subjected to an acute and total asphyxial insult (its umbilical cord was ligated and a saline-filled bag placed over its head). The monkey made initial rapid breathing efforts but

Fig. 13.1 Illustration (reputedly of Dr Bernhard Schultze himself) demonstrating the Schultze method of neonatal resuscitation. (Reproduced from Schultze (1871).)

these were ineffective because of the bag. Figure 13.3 is a hand-drawn representation of what was recorded. The heart rate (HR) fell, the animal became more acidaemic and hypotensive and breathing efforts ceased. The animal slid inexorably toward death unless it was revived by endotracheal PPV. This resulted in a prompt increase in HR with recovery in acid–base status and blood pressure and was followed by a return of spontaneous respiration. These studies were responsible for PPV becoming the mainstay of neonatal resuscitation and underpin neonatal resuscitation practice in the delivery room to this day.

Formal courses teaching neonatal resuscitation evolved in the 1980s, notably the Neonatal Resuscitation Program in the USA (Kattwinkel 2006) and the Newborn Life Support Course in the UK (Richmond 2006). These courses taught the causes and physiology of neonatal asphyxia and response to resuscitation described by Dawes. They taught a structured approach to assessing and assisting newborns that was agreed to be ‘accepted practice’ by ‘experts in the field’ but based on little hard evidence. Doctors, midwives and nurses have attended these courses in ever-increasing numbers, and attendance at such courses is mandatory for physician training in many countries. In 1996, the International Liaison Committee on Resuscitation (ILCOR), a body representing resuscitation societies around the world, made recommendations for resuscitation of all age groups. The first guidelines to make specific recommendations for newborns were published in 1999 (Kattwinkel et al. 1999). First convened in 2000 (Contributors and Reviewers for the Neonatal Resuscitation Guidelines 2000), the Neonatal Task Force of ILCOR has reconvened at 5-yearly intervals to assess neonatal resuscitation research and update the guidelines accordingly (The International Liaison Committee on Resuscitation 2006; Perlman et al. 2010).

Epidemiology of neonatal resuscitation

It is estimated that up to 10% of newborns receive some help to establish regular breathing at birth, making respiratory support one of the most commonly performed medical interventions (Perlman et al. 2010). The rates of late fetal death, stillbirth, birth asphyxia and perinatal sepsis are higher in developing countries than in developed countries; consequently, term infants are more frequently resuscitated in developing countries. The more immature an infant, the higher the chance that respiratory support after birth will be needed. In developed countries, preterm birth occurs more frequently than birth asphyxia; hence premature infants constitute the majority who receive respiratory support and resuscitation.

The approach to newborn resuscitation

While most babies require either no or minimal resuscitation, it is important to be prepared for babies who may need resuscitation. Ask about the history of the pregnancy and labour, as many easily identifiable features increase the risk that the baby will need help after birth (Box 13.1).

About 25% of depressed babies are undiagnosed before birth. This is why everybody who has the responsibility of caring for a neonate must be trained in basic resuscitation techniques.

Always check the equipment before the baby is born.

Newborns have problems that make respiratory support and resuscitation fundamentally different from other ages:

- Their lungs are full of ‘lung liquid’ and have never been aerated.

Fig. 13.2 Scheme showing the response of an asphyxiated Rhesus monkey to resuscitation. (Reproduced from Dawes 1968.)

- Preterm infants have a very compliant chest wall that distorts with their inspiratory efforts.
- In the first few minutes the oxygen saturation is lower and they appear cyanosed.

Many adults needing resuscitation do not have a heart beat or breathe adequately, because they have cardiac dysrhythmia caused by an acute coronary event. Circulatory support with chest compressions, cardioversion and/or drugs is the priority when resuscitating adults (Hüpfel et al. 2010). When a baby's heart beat is slow or absent it is due to progressive myocardial acidaemia and hypoxia, not an acute dysrhythmia. The acidaemia and hypoxia cannot be corrected by chest compressions, adrenaline (epinephrine) or

Box 13.1 Factors that increase the risk that the baby will need help after birth

Prematurity	The more immature the baby, the more likely he or she will need help
Antepartum haemorrhage	This is usually mother's blood. However, it can be baby's blood. Rarely, the baby may have exsanguinated (vasa praevia) Some fetal haemorrhages are concealed, e.g. fetomaternal, retroplacental or subgaleal (subaponeurotic)
Signs of fetal compromise	Oxygenation of the baby's vital organs may be compromised
Heavily meconium-stained liquor	The baby may be very hypoxic and depressed. He or she may have been gasping in utero and inhaled meconium
Very small-for-dates babies	These babies may not cope with the stress of labour
Maternal general anaesthetic	The baby may not breathe spontaneously
Congenital abnormality affecting the lungs	For example diaphragmatic hernia, cystic adenomatoid malformation. Baby may not breathe effectively
Hydrops fetalis	The chest wall may be oedematous and stiff and pleural effusions and ascites may compromise breathing
Intrauterine infection	The lungs may be stiff with congenital pneumonia
Mechanical factors	Prolapsed cord, difficult forceps delivery, cephalopelvic disproportion, breech delivery, shoulder dystocia, precipitate delivery and prolonged labour all increase the chance of oxygenation being compromised
Prolonged rupture of the membranes >3 weeks	If the membranes have been ruptured with little liquor the lungs may not develop properly and lung hypoplasia can occur
A large baby	The delivery may be difficult

cardioversion alone or in combination. In newborns the acidaemia and hypoxia are treated by aerating the fluid-filled lungs and establishing gas exchange. The priority in neonatal resuscitation – even when faced with an absent heart beat – is *always* to provide respiratory support.

Assessment of the newborn

In 1953, an American anaesthetist, Dr Virginia Apgar, proposed a method of evaluating newborns to 'compare the effect of obstetric and anesthetic interventions' (Fig. 13.3). The Apgar score is the sum of values 0–2 assigned for each of five items (breathing, HR, colour, tone and reflex irritability) 1 minute after birth. Later the score was routinely assessed at 5 and 10 minutes of life. At the outset, Apgar stated that each element of the score was not of equal importance, but thought that weighting the score would make it cumbersome and less likely to be applied (Apgar 1953). She believed the score

Fig. 13.3 Dr Virginia Apgar's original paper describing her method for evaluating newborns. (Reproduced from Apgar 1953.)

would be useful for comparing populations of infants but that it would be neither sensitive nor specific enough to prognosticate in individual infants (Apgar 1966). In the early 1950s, newborns were largely ignored in the delivery room (Apgar remarked at the time that 'surely nine months' observation of the mother merits one minute's observation of the baby'; Apgar 1966). The Apgar score was hugely important in drawing attention to infants in the delivery room and, more than 50 years later, it is still universally recorded.

The Apgar score is now used for purposes for which it was not intended. Although persistently low Apgar scores are associated with poor neurological outcome in populations, the predictive value of low Apgar scores for individual infants is poor (O'Donnell et al. 2006b). It is relatively easy to calculate the Apgar score for healthy infants but there is disagreement on how to score premature infants and those receiving respiratory support (Lopiere et al. 2004). As the Apgar score is subjective there is considerable inter-observer variability in how scores are assigned, which makes it somewhat inaccurate (O'Donnell et al. 2006b).

Muscle tone

In adults and older children, tone is assessed by examining passive resistance to movement of the limbs over one or more joints for a

minute or more. In contrast, a newborn's tone is assessed in seconds by observing posture and movements. Tone is the first sign that can be evaluated. Though the quality of an infant's tone is subjective and varies with gestational age, it is an important and frequently underrated sign. Healthy newborns have a flexed posture that is most notable at the hips, knees and elbows (Ch. 40.1); the degree of flexion increases with maturity. Whatever the gestation, a baby with flexed posture or who is moving the limbs has reasonable tone and is not seriously asphyxiated. Clinicians presented with a baby with a flexed posture can thus be reassured and proceed with less haste. A baby who is limp is more likely to be in poor condition and needs immediate close attention.

Spontaneous breathing

For such a fundamental act it is surprising how little is known about how babies begin to breathe after birth. Many infants, even the most immature, cry shortly after delivery. Others may not cry but breathe independently, albeit irregularly, at birth. Breathing movements in babies may be subtle and movement of the abdomen, due to diaphragmatic contraction, is often more easily seen than chest excursion. The majority of newly born very premature babies breathe at birth. MacDonald et al. (1980) reported that 72% of babies of 27–28 weeks' gestation, born in the early 1970s, had sustained breathing at 1 minute of age without PPV. Among infants <28 weeks born in the modern era, about 70% cry and 80% breathe spontaneously after birth (O'Donnell et al. 2010).

Relatively little is known about the nature of the initial breathing. Karlberg et al. (1962) reported that among 18 well term newborns the time of onset of breathing varied from 3 to 80 seconds; the inspired tidal volume varied from 12 to 67 mL (approximately 3.5–14.7 mL/kg), and they often used a negative pressure up to 70 cmH₂O. te Pas et al. (2009b) described patterns of breathing where preterm and term infants take quick large inspirations, followed by prolonged expiration, usually achieved by crying or laryngeal adduction, associated with contraction of the abdominal muscles causing a high intrathoracic pressure during most of expiration. The presumption is that this 'expiratory braking' helps to establish and maintain a functional residual capacity (FRC). A baby's respiratory efforts are rarely directly measured during neonatal resuscitation and the efficacy of breathing is largely judged by its effect on the infant's HR. An infant's breathing efforts must be sufficient to ensure a HR >100 beats per minute (bpm) (Contributors and Reviewers for the Neonatal Resuscitation Guidelines 2000).

Breathing difficulty may present at or shortly after birth. Many of the signs – intercostal, subcostal and sternal recession – are due to the powerful diaphragm exerting its influence on the newborn's pliable thoracic cage as it tries to draw air into relatively stiff (poorly compliant) lungs. Expiratory grunting during expiration has long been recognised as a sign of respiratory difficulty. Harrison et al. reported in 1968 that when infants who were grunting were intubated the grunting ceased; however, the oxygen in their arterial blood (P_{aO_2}) fell. When the endotracheal tube (ETT) was removed, grunting resumed and the P_{aO_2} increased. This demonstrated that grunting is a mechanism infants use to preserve their lung volume and create an FRC by generating positive end-expiratory pressure (PEEP) by partially closing their larynx during a forced expiration (see PEEP below).

Heart rate

HR is the most sensitive indicator of a newborn's condition and it increases rapidly in bradycardic infants with effective resuscitation

Fig. 13.4 Centiles showing heart rate measured with a pulse oximeter of infants who were not resuscitated at birth. (Reproduced from Dawson *et al.* (2010a).)

(Fig. 13.3). Clinically, HR is best determined by listening to the chest with a stethoscope (auscultation). The number of beats in 6 seconds is multiplied by 10 to give the HR in bpm (Kattwinkel 2006). A short interval – far shorter than the 15–60 seconds used to count HR in older children or adults – is thought necessary because the HR is more rapid and changes quickly in newborns. This has the disadvantage that errors are increased 10-fold and so can be inaccurate (Kamlin *et al.* 2006). The HR can sometimes be counted by feeling umbilical cord pulsations, but, as they are often impalpable, auscultation is superior to cord palpation, which is no longer recommended. Neither provides information readily available to the resuscitation team, leading to some advocating that the person listening to the HR ‘tap it out’ with a finger as a visual cue. Resuscitative efforts may be interrupted to allow the HR to be determined by auscultation, which is not ideal. It is taught that the HR should be counted every 30 seconds. However, this does not enable a dynamic assessment of the HR changes. Many of these problems may be addressed by using a pulse oximeter (see below), which is now recommended by ILCOR (Perlman *et al.* 2010).

It is taught that an infant’s HR should be >100 bpm after birth; that respiratory support should be given if the HR is <100 bpm; and that chest compression should also be given if the HR is <60 bpm (Kattwinkel 2006). In reality, well term newborns who are not resuscitated frequently have a HR <100 bpm in the first 2 minutes after birth, which rapidly increases with time (Fig. 13.4; Dawson *et al.* 2010a). For babies who have reasonable tone and who are crying or making breathing efforts, HR <100 bpm on its own is not an indication for intervention. However, if a baby is limp, not breathing and the HR is <100 bpm, PPV is needed. If the HR does not increase promptly, the most likely reason is that the PPV is ineffective. Before chest compression is started, it is imperative that ventilation is optimised. If the baby remains bradycardic despite ventilation with PEEP (see later) moving the chest, then chest compressions should be given. However, the most likely reason for

continued bradycardia is that the respiratory support is inadequate (Perlman and Risser 1995).

Colour

Compared with adults, children and older infants, the fetus has low P_{aO_2} (~2–3 kPa) and oxygen saturation of haemoglobin in arterial blood (S_{aO_2} , ~50%); hence newborns appear cyanosed immediately after birth. As they aerate their lungs and establish gas exchange, the peripheral oxygen saturation (S_{pO_2}) increases over the next few minutes and they look increasingly pink. They first look pink centrally – i.e. their tongue, lips, face and torso – while their peripheries (arms and legs) become pink later. There is substantial interobserver variability in the determination of pinkness and this determination correlates poorly with an infant’s S_{pO_2} (O’Donnell *et al.* 2007). It takes normal newborns several minutes to achieve an S_{pO_2} >90% (Fig. 13.5; Dawson *et al.* 2010b). It is less important to decide whether or not an infant is pink than to determine oxygenation is improving (becoming ‘pinker’) with time. In the minutes after birth, the oxygenation of a baby receiving respiratory assistance is best measured using a pulse oximeter with the sensor on the right wrist (see below).

Occasionally babies are born very pale. These babies are usually also limp and bradycardic. This sickly yellowish colour signifies poor circulation and acidosis. These babies must be resuscitated without delay, and help will be required. Even more rarely, babies are born a ghostly, milky-white colour. These infants may have better tone and be more responsive than one would expect for an asphyxiated infant. Despite adequate PPV some have bradycardia that responds quickly to infusion of volume. These babies may have had an acute haemorrhage, which is usually heralded by a large antepartum haemorrhage (e.g. placental abruption, vasa praevia), but may be concealed because it was due to a fetomaternal haemorrhage. These babies may require urgent blood transfusion,

Fig. 13.5 Centiles showing oxygen saturation measured with a pulse oximeter of infants who were not resuscitated at birth. (Reproduced from Dawson et al. 2010b.)

and on occasion a transfusion of uncrossmatched O-negative blood in the delivery room can be life-saving.

Pulse oximetry

A pulse oximeter measures both HR and SpO_2 using a sensor that has a light-emitting diode and a detector placed in opposition around a baby's hand or foot. See Chapter 19 for more information on this method of monitoring.

When placed preductally (on the right wrist) oximeters can give data about 20 seconds after the sensor has been applied correctly. If placed immediately after birth a signal can usually be obtained by 90 seconds (O'Donnell et al. 2005a). Pulse oximeters count the HR more accurately than clinicians listening with a stethoscope or feeling the umbilical cord (Kamlin et al. 2006). In addition, the HR is counted accurately (Kamlin et al. 2008) and displayed continuously, non-invasively and without the need for resuscitation to be interrupted. Fuelled by uncertainty about using oxygen during neonatal resuscitation, pulse oximeters in the delivery room are now advocated by ILCOR (Perlman et al. 2010).

Interpreting the changing SpO_2 data immediately after birth requires knowledge of the normal changes with time. The preductal SpO_2 of newborns who do not need resuscitation has a wide range and increases during the first 10 minutes. At 1 minute the median (10th and 90th centiles) is 66% (33%, 85%), at 5 minutes it is 89% (72%, 97%), and at 10 minutes it is 96% (87%, 99%) (Fig. 13.5; Dawson et al. 2010b). Babies born prematurely or by caesarean section (CS) have lower SpO_2 than those born vaginally at term and it increases more slowly. The appropriate SpO_2 for an infant at any given time – or more pertinently, the value which suggests that the SpO_2 is too low and O_2 should be given – is not yet clear. The recent publication of centile charts (Fig. 13.5) has been very helpful in illustrating the normal range for babies who did not require resuscitation (Dawson et al. 2010b). The appropriate inspired oxygen for infants (particularly preterm) who receive respiratory support at birth is still being investigated. We suggest a target is to keep the SpO_2 >10th centile and <90th centile targets. There is good evidence

from animal studies that hypoxia on its own does not cause brain damage. Hypoxia with hypotension and bradycardia is potentially damaging.

Techniques of resuscitation

Delivery-room stabilisation and resuscitation comprise interventions to minimise the infant's heat loss, and provide respiratory and circulation support, as determined by ongoing assessment of their clinical condition. Measures are taken to reduce heat loss for all babies. Respiratory support is the key to neonatal resuscitation and is always the priority for infants in poor condition at birth. Circulatory support is rarely needed (Wyckoff et al. 2005).

Figure 13.6 shows the ILCOR algorithm, on which most other algorithms are based.

Thermoregulation

Hypothermia can cause respiratory compromise, acidosis, circulatory collapse and death in newborns of any gestation. It is of particular concern for premature babies who have less insulation (body fat) and bulk (energy stores) and are more skinny (greater body surface area:body mass ratio) than their term counterparts. Maintaining the body temperature of preterm infants in 'the thermoneutral zone' (36–37°C, the range in which the infant's metabolic demands were least) substantially reduced mortality, and remains a key plank of neonatal care (Ch. 15) (Silverman and Sinclair 1966).

Though less common than hypothermia, there is an association between hyperthermia after birth and poor neurodevelopmental outcome. Whether this is because hyperthermia is largely due to chorioamnionitis, itself associated with adverse neurological outcomes, or because there is an independent effect of high temperature is unclear.

Therapeutic hypothermia for term babies with a recent hypoxic-ischaemic insult is an effective therapy which is discussed in

Fig. 13.6 Adapted from International Liaison Committee on Resuscitation algorithm for resuscitation. CPAP, continuous positive airway pressure; ETT, endotracheal tube; HR, heart rate; PPV, positive-pressure ventilation.

Chapter 40, part 4 (Jacobs et al. 2007). If a baby is born who is likely to fit the criteria for treatment with therapeutic hypothermia, i.e. apnoeic, requiring respiratory support through an ETT at 10 minutes, low pH of cord blood, it is reasonable to turn off external heat sources (e.g. radiant warmers) to allow the infant to cool passively. However, the baby's temperature must be closely monitored as it is surprisingly easy to cool these infants more than to the intended level of 33.5°C.

Strategies to keep newborns in the thermoneutral range usually combine measures to provide heat and to reduce heat loss. The simplest external heat source is the mother's body. Babies may be placed directly (skin to skin) on the mother's chest and covered with a blanket or towel.

To minimise heat loss, babies should be delivered in a warm room (the World Health Organization recommends 25°C). Evaporative heat loss is a particular concern for all newborns as they are naked and wet at birth (Ch. 15). Term babies should be dried and covered with a hat. If there is concern about keeping a baby warm, heated blankets or a radiant heat source can be used. In general these measures are adequate for term babies. However, despite these measures, hypothermia on admission to the neonatal intensive care unit (NICU) was common among extremely preterm babies in the UK in the mid-1990s (40% of infants <26 weeks <35°C) and the risk of death and disability was increased among these infants (Costeloe et al. 2000). Several randomised trials have examined the effect of placing very premature babies, directly after birth, in clear plastic (food-grade polyethylene) bags without first drying them. These showed significant increases in temperature on admission to the NICU (Vohra et al. 1999, 2004). Polyethylene wrapping exploits a simple principle – light in the infrared spectrum (i.e. heat) is admitted through the polyethylene, while evaporative heat loss is reduced (impressive misting is seen on the inside of the wrap). Polyethylene wrapping has been recommended for reducing hypothermia among preterm infants (Perlman et al. 2010). It is worth noting, however, that overheating is possible, so it is prudent to check the baby's temperature if he or she remains under radiant heat in a plastic bag for protracted periods. More recently, Trevisanuto et al. (2010) demonstrated that a polyethylene cap was as effective as polyethylene wrapping and both were more effective than drying for preventing hypothermia in preterm infants placed under radiant heat. Exothermic mattresses are used as a heat source to prevent hypothermia in preterm infants. The effect of any of these interventions – polyethylene bags, polyethylene caps and exothermic mattresses – in combination is unclear.

Airway management

Compared with humans of other ages, newborns have relatively large heads and floppy airways. Though babies with respiratory difficulty are often placed prone in the nursery to improve their breathing, it is recommended that, immediately after birth, infants are placed supine on a firm surface (Kattwinkel 2006), although this is not evidence-based. It is recommended that the head is held in a 'neutral' (neither flexed nor extended) or 'sniffing' position; and, if the infant is not breathing, that 'jaw thrust' – gently pushing the baby's mandible forward with fingers placed behind the angles of the jaw – is used as a means of opening the airway (Kattwinkel 2006; Richmond 2006). When attempting to maintain an open airway during spontaneous breathing or respiratory support, try not to press on the soft tissues under the chin as this may predispose to airway obstruction by the tongue.

Newborns are frequently suctioned because clear fluid comes from their mouths. Fetal lungs are filled with liquid. Production of

lung liquid ceases during labour and infants expel the liquid from the airways and reabsorb it from the lungs after birth. It is normal for clear fluid to well up from the trachea and appear in the oropharynx. There is no evidence that routine suction of the airways after birth aids a baby's breathing. The use of a standard suction catheter vaguely poked into a baby's mouth will not clear blood clots or pieces of meconium. Blindly suctioning the naso- and oropharynx of well infants with a suction catheter may cause harm by inducing vagally mediated bradycardia, laryngospasm or local trauma and should be avoided. If blood or meconium is thought to be obstructing the airways it should be removed under direct vision, using a laryngoscope and a large suction catheter. Complete airway obstruction is rarely a cause of collapse in newborns, and, when it does occur, the obstruction is usually due to an anatomical anomaly (e.g. large cystic hygroma, tracheal agenesis) that is not remediable by suction. Suction may be needed if fluid or meconium obscures the view when attempting endotracheal intubation.

Suction may be indicated when a non-vigorous infant is delivered through meconium-stained liquor (see Special circumstances, meconium-stained liquor, below).

Oropharyngeal (Guedel) airways have previously been recommended for use in newborns. These were developed for adults with depressed consciousness. While models for term babies are available, they are not suitable for very preterm infants. Studies of their use in newborns have not been reported. Laryngeal masks have been used for near-term infants with upper airway anomalies. Infants with the Pierre Robin sequence have very small chins (micrognathia). When these infants are placed supine, the tongue may obstruct the airway (glossoptosis). These infants should be nursed prone to help reduce the obstruction. Should this prove ineffective, a nasopharyngeal airway should be used. This may be a specifically designed device or an ETT of diameter appropriate for the infant's weight shortened to the distance from the infant's nose to the angle of the mandible. The aim of these devices is to maintain airway patency by relieving tongue obstruction.

Respiratory support

At birth, placental support is removed and the newborn must use the lungs to exchange gas. To do so effectively, the lung fluid must be rapidly cleared, air must enter the lungs and the blood flow through their lungs must increase. Gas exchange is a continuous process, with oxygen and carbon dioxide diffusing across pulmonary capillary membranes throughout the respiratory cycle, whether the baby is breathing in or out. For this to occur it is critical that the infant has an adequate volume of gas in the lungs at the end of expiration, i.e. an FRC. Mechanical stretching as gas enters and is retained within the lung and increased oxygen tension in the alveoli provoke profound vasodilation in the pulmonary vascular bed. The consequent drop in the pulmonary blood pressure results in a large increase in pulmonary blood flow, which allows gas exchange to occur. These physiological changes are most commonly achieved by spontaneous breathing. Occasionally infants are apnoeic or breathe inadequately. The key to successful stabilisation or resuscitation is to establish effective ventilation.

The aim of respiratory support is to assist spontaneous breathing with continuous positive airway pressure (CPAP) through a mask or nasal prongs, or, if the baby is apnoeic, give PPV with a face mask, through nasal prongs or an ETT.

It is critical for effective gas exchange that newborns quickly achieve and maintain an FRC. The key determinant of FRC in ventilated infants is the mean airway pressure (MAP). MAP is determined mainly by the CPAP or PEEP as it is applied for about two-thirds of the respiratory cycle. The peak inflating pressure (PIP)

also affects MAP, but to a lesser extent than PEEP, as it is applied for about one-third of the respiratory cycle.

For adequate gas exchange babies need to breathe in and out a tidal volume (V_T) of gas of $\sim 4\text{--}8$ mL/kg body weight. The V_T that enters the lung is determined principally by the spontaneous inspiratory effort and to a lesser extent by the PIP during PPV. See [Chapter 27 part 1](#) for more information on respiratory physiology.

Expired air ventilation

Mouth to mouth, or more often mouth to mouth and nose, assisted ventilation was advocated in early resuscitation guidelines. It was recommended that resuscitators placed their mouth around the mouth, or mouth and nose, of apnoeic newborns and breathe into the baby sufficient to produce a gentle rise of the baby's chest. [Tonkin et al. \(1995\)](#) demonstrated that most mothers' mouths are not large enough to encircle their infant's mouth and nose, and speculated that mouth to nose resuscitation may be a better alternative. No human studies of any of these techniques have been reported and they are rarely used in developed countries, where manual ventilation devices are available. In places where manual ventilation devices are not available, mouth to mask resuscitation, rather than mouth to mouth/nose, is recommended to reduce the risks of transmitting infections ([Perlman et al. 2010](#)).

Continuous positive airway pressure

Most babies, even the most immature, breathe or cry at birth ([O'Donnell et al. 2010](#)). If they are very preterm or have obvious respiratory difficulty, with marked sternal recession or irregular breathing, it is important to help them quickly aerate their lungs and facilitate early gas exchange. This is done by providing CPAP as soon as they start breathing. CPAP aids lung aeration, lung fluid clearance and the formation of an FRC and improves oxygenation. CPAP can be given through a face mask or nasal prongs attached to a T-piece device. The pressure should be no less than 5 cmH₂O and immediately after birth, while the lung fluid is being cleared, a pressure up to 8 cmH₂O may help. Self-inflating bags (SIBs) and flow-inflating bags (FIBs) cannot be used to provide consistent CPAP.

Aerating the lung and forming an FRC are the most important first steps in any resuscitation. Because this improves gas exchange it should be used before the inspired oxygen is increased. Treating a baby with supplementary oxygen will not be effective if the lung volume is very low. Several randomised controlled trials, enrolling very preterm infants, have shown that early CPAP is very effective for at least half the babies who do not require intubation ventilation or surfactant and have an outcome that is at least as good as babies who are routinely intubated at birth ([Morley et al 2008](#); [SUPPORT Study Group 2010](#)).

Positive-pressure ventilation

PPV is indicated from birth if the infant is apnoeic. In general, PPV is started with a face mask. Mask ventilation is usually only needed for a few minutes. Most infants who receive mask ventilation subsequently breathe. Those who do not breathe should be intubated and ventilated.

Face masks

Face masks are the interface most commonly used to give PPV to newborns. While there are few studies to determine which type of mask is superior, round silicone masks with a cushioned rim are

the most commonly used model ([O'Donnell et al. 2004](#)). Round masks are better than Rendell-Baker masks (solid triangular masks without a rim that were developed for inhalational anaesthesia) ([Palme et al. 1985](#)). Face masks should encircle the infant's mouth and nose, but not encroach on the eyes ([Kattwinkel 2006](#)); and different sizes are available. During inflations, in mannikin studies ([O'Donnell et al. 2005b, c](#); [Wood et al. 2008a, b](#); [Tracy et al. 2011](#)) and in infants during resuscitation ([Schmölzer et al. 2010](#)) there are gas leaks from face masks which are often large and variable and can interfere with effective resuscitation.

The way the mask is positioned and held is important ([Wood et al. 2008b](#)). With a round Laerdal-type face mask it is important to use the two-finger-top hold with chin lift. The mask is rolled on to the face from the chin and held in place with the thumb and first finger placed either side of the stem, exerting an even pressure vertically downwards. The second and third fingers are placed under the mandible and pull the jaw upwards with an equal pressure to the downward force on the mask. This can be learned by good education and practice ([Wood et al. 2008b](#)). The mask must not be held around the rim as this can cause it to kink and leak badly. If ventilation is still is not effective a good seal may be obtained with a two-handed technique to hold the mask in position and a second person doing the inflations ([Tracy et al. 2011](#)). While tidal volumes adequate for gas exchange are often not delivered to infants during mask PPV ([Milner et al. 1984](#)), it may be sufficient to stimulate the baby to breathe spontaneously.

Airway obstruction occurs during mask ventilation ([Finer et al. 2009](#); [Schmölzer et al. 2011](#)). When babies do not respond to mask ventilation, measures should be taken to ensure the airway is patent (e.g. checking the mask position and hold, repositioning the head, jaw thrust, suctioning the airway) and that enough PIP is being used before continuing with mask ventilation. Infants who still do not respond to mask ventilation with a pressure of 30 cmH₂O should be intubated for further PPV ([Perlman et al. 2010](#)).

Nasal airways

Infants are primarily nose breathers. Though CPAP is often given to preterm infants via nasal prongs for prolonged periods in the neonatal nursery, respiratory support is less frequently given to newborns with nasal prongs in the delivery room. The use of a nasal tube (an ETT of appropriate internal diameter shortened to ~ 5 cm; also known as a nasopharyngeal tube, single nasal prong, short tube) in preference to a face mask for preterm infants was associated with a halving in the rate of intubation in the delivery room in a retrospective cohort study ([Lindner et al. 1999](#)) and with a reduction in the rate of mechanical ventilation within 72 hours in a randomised trial ([te Pas and Walther 2007](#)). As the nasal tube was only one of a number of differences in the treatment of the groups in both studies, it is difficult to determine the contribution of the nasal tube to the differences in outcomes observed between the groups.

If a short nasal tube is used, it is important that it is placed in the nostril at right angles to the face and angled back over the soft palate. Nasal tubes should not be pushed up the nose (caudally) as they can pierce the cribriform plate and cause brain injury. Binasal cannulae were superior to the seldom-used Rendell-Baker face mask in a randomised trial enrolling term and near-term infants ([Capasso et al. 2005](#)). Studies comparing nasal airways to face masks for respiratory support in the delivery room are ongoing.

Laryngeal mask airway

Laryngeal mask airways (LMAs) were developed as an alternative to ETTs to support the breathing of adults undergoing short periods

of general anaesthesia. They are designed to fit over the laryngeal inlet and can be placed quickly without the need for a laryngoscope. Once inserted, a cushioned rim is inflated to achieve a seal. LMAs offer a more stable airway than a face mask and are easier to place correctly than ETTs, even by relatively inexperienced operators. They were designed to be used with patients with normally compliant lungs, not with the stiff lungs frequently encountered in newborns. The use of LMAs has been reported in case series of term infants (Gandini and Brimacombe 1999a) and in small numbers of moderately preterm infants (Gandini and Brimacombe 1999b). The use of LMAs in newborns is limited, at least in part owing to the lack of sizes small enough for infants weighing less than 2 kg, who constitute the majority of infants being resuscitated. Successful use of LMAs in the setting of upper airway anomalies has been reported (Gandini and Brimacombe 2003). It may thus be prudent to have a neonatal LMA available for use in exceptional circumstances and for people to be trained in its use.

Endotracheal tubes

When infants fail to respond to PPV by face mask, or are judged to need ongoing respiratory support, they should be intubated and ventilated. ETTs used in newborns are sterile, single-use plastic tubes with a uniform diameter. In contrast to those used for children and adults, ETTs for newborns do not have an inflatable cuff. 'Shouldered' Cole's ETTs – tubes with a narrow distal diameter that passes through the vocal cords, and a wider proximal diameter – are now rarely used. ETTs are sized by their internal diameter, with the appropriate size determined by the weight or gestation of the infant (2.5 mm for infants <1000g / ≤27 weeks; 3.0 mm for 1–2 kg/28–36 weeks; 3.5 mm for >2 kg/near term). They are usually marked at 1-cm intervals from the tip and have a black line that acts as a guide to insertion depth. The insertion depth is often determined by the infant's weight (depth of insertion at lips for oral ETTs (cm) = 6 + (infant's weight in kg), e.g. for a 1.5-kg baby, approximate depth of insertion = 7.5 cm at the lips); or may be more accurately estimated from the gestational age (Table 13.1; Kempley et al. 2008).

Intubation technique

ETTs are passed through an infant's vocal cords into the trachea under direct vision using the light from a laryngoscope placed in the mouth. ETTs may be introduced through either the mouth or

nose (Ch. 44) but oral intubation is generally used at resuscitation. Laryngoscopes are designed to be held in the left hand (irrespective of the handedness of the user) and consist of a handle, a blade set at right angles to the handle and a light mounted on the blade. Before attempting intubation, ensure that the light is adequately bright.

The most important part of the laryngoscope is the blade. The laryngoscope blades used in newborns are usually straight (occasionally curved) and come in different sizes, with suitability determined by the size of the infant (size 00 for infants <1 kg, 0 for infants 1–3 kg, 1 for infants >3 kg). It is critical that the blade chosen is long enough. If it is too short to reach the epiglottis, you will not be able to see the vocal cords and will not successfully intubate the baby. The objective is to insert the blade into the mouth, to advance it to the epiglottis, to place the tip in the vallecula, and to lift up the epiglottis gently to see the larynx. Hold the laryngoscope towards the left side of the mouth and ensure that the tongue is out of the way to give enough room to see past it and insert the ETT. Once in position, the laryngoscope should be gently raised, i.e. lifted in the plane of the laryngoscope's handle, not pivoted backwards using the upper gum as a fulcrum (the function of the handle is to hold the batteries, not to act as a lever). Wait until the vocal cords open – do not attempt to force the tube through adducted cords – and then advance the ETT until the top of the black line is still seen. If the larynx is difficult to see, press it down with your left little finger or ask someone else to press it down. Once the ETT is in place, hold it with the thumb and index finger of the right hand and curl the other fingers round the baby's face to keep the ETT in position. *Don't let go* for any reason until it is firmly secured in position.

Once an ETT has been passed, the operator must confirm that it is correctly placed in the trachea. This has been traditionally done using clinical signs. The most sensitive indicator is the HR, which increases promptly in bradycardic infants given PPV through a correctly placed ETT. Other signs sought to confirm correct placement are air entry audible with a stethoscope over both hemithoraces; appearance of condensation on the inside of the ETT during expiration ('mistings') and visible chest rise (Kattwinkel 2006). All of these signs are subjective and their sensitivity and specificity are difficult to determine. In preterm infants in particular, air movement can be heard widely throughout the chest even if the ETT is in the oesophagus. Also, if the chest of a preterm newborn can easily be seen to move with PPV, it is likely that the lungs are being overdistended.

ILCOR recommends using colorimetric exhaled CO₂ detectors after each intubation to confirm ETT placement (Perlmán et al. 2010). These devices are placed between the ETT and the ventilation device and change colour from purple to yellow in the presence of exhaled CO₂. They identify correctly placed ETTs much quicker than clinical assessment alone (Aziz et al. 1999). If the detector does not change colour, the most common reason is that the ETT is not in the trachea. However, a detector may not change colour during PPV through a correctly placed ETT if the infant's lungs are poorly compliant with little/no tidal volume moving because the PIP is too low to inflate the lungs (Kamlin et al. 2005), or if there is cardiac arrest and no circulation in the lungs (Aziz et al. 1999).

Once it is confirmed that the ETT is in the trachea, an appropriate depth of insertion should be rechecked (see above). The tube should then be firmly secured. The position should be checked with a chest X-ray, the aim being to have the ETT tip beneath the vocal cords and above the carina (approximately T1–T4).

Intubation is an important skill that may be difficult to acquire. Babies are being intubated less frequently and doctors in training have shorter working hours than before. As a result trainees are getting fewer opportunities to master the skill (Leone et al. 2005). It

Table 13.1 Oral tracheal tube lengths by gestation

has been recommended that infants should be intubated within 20 seconds (Kattwinkel 2006). However, it often takes considerably longer (Lane et al. 2004; O'Donnell 2006). The success rate of doctors attempting intubation in the delivery room is about 50% (O'Donnell 2006). Intubation has many unwanted effects, both in the short term (failure, bradycardia, hypoxia, raised intracranial pressure, mouth, laryngeal or tracheal injury) and longer term (subglottic stenosis, chronic lung disease). In contrast to infants in NICU, newborns in the delivery room do not receive premedication before intubation. This may make delivery room intubation more difficult and probably increases the occurrence of short-term side-effects. Plastic ETTs become pliable when warm so they should not be placed under the radiant heater. Some operators use introducers (or stylets) – sterile plastic-coated wires placed in the ETT lumen to make it more rigid – when attempting intubation. Tracheal injury has been reported from introducers and correctly placed ETTs may be accidentally dislodged when removing the introducer. A randomised trial did not show any difference in the rate of successful intubation by groups of trainees when an introducer was used (O'Connell and Kamlin). If introducers are used, they must not protrude beyond the end of the ETT. A fresh ETT should be available for each potential intubation, as ETTs that are opened and not immediately used become colonised with bacteria (Walsh et al. 2008).

Achieving an airway is of critical importance. However, intubation by itself does not save lives; it is the effectiveness of the ventilation that counts.

Ventilation devices

Mechanical ventilators are used to give infants PPV in the NICU. These give inflations with a duration (T_i), PIP, PEEP and frequency (rate) that are set and controlled by the machine. Most modern ventilators incorporate a flow sensor that measures the tidal volumes of gas entering and leaving the ETT. Mechanical ventilators are, however, rarely used in the delivery room. Instead, manual ventilation devices are generally used. Different types of devices are available, each with different characteristics. The operator controls the parameters that are usually set on a mechanical ventilator. No manual ventilation device incorporates a flow sensor.

Self-inflating bags

The SIB is the most commonly used device (O'Donnell et al. 2004). It does not need a compressed gas source to function, though one is often attached to allow supplemental oxygen to be delivered. SIBs come in a variety of sizes, including those designed for newborns (240–500 ml).

The PIP delivered with a SIB is determined by how hard the bag is squeezed. It is not usually measured, though a manometer may be added to the circuit. SIBs usually have a pressure-limiting 'pop-off' valve, designed to open when a given pressure (often 40–50 cmH₂O) is exceeded. These valves open at widely varying pressures in vitro (Kanter 1987) and very high pressures can be delivered by occluding the pop-off valve with a finger or thumb. The T_i is variable and can be very short. The greatest problem of the SIB is that CPAP cannot be delivered. When a PEEP valve is added, a very variable decelerating PEEP is produced only if the inflation rate is at least 40/min. This is particularly relevant when ventilating intubated babies, especially if they are premature. When the larynx is bypassed with an ETT, the baby cannot generate endogenous PEEP, which compounds the difficulty of achieving an FRC.

Anaesthetic (flow-inflating) bags

FIBs need a compressed gas source to inflate. Limiting the rate of gas escape through the 'tail' of the bag generates PEEP. Gas flows

toward the infant when the bag is squeezed. The force with which the bag is squeezed determines the PIP, and very high PIP can be generated. The T_i is determined by the duration of the squeeze. FIBs require a greater degree of operator skill to deliver targeted pressures than SIBs or T-pieces (Bennett et al. 2005) and are less frequently used in Europe than in the USA (Leone et al. 2006). They cannot be used to deliver consistent CPAP.

T-piece devices

T-piece devices need a compressed gas source, which has been pressure-limited to a pressure suitable for the newborn. Tubing with gas flow forms the 'upstroke' of the 'T'. At one end of the 'crossbar' there is the patient outlet fixed to a face mask or ETT; at the other is a valve that controls the rate of gas escape from the system. CPAP or PEEP is generated by altering the rate of gas escape through this valve. PIP is generated by occluding the valve. The PIP and PEEP delivered are set by the operator and are more stable than that delivered with an SIB or FIB (Bennett et al. 2005). This stability of set pressures is considered one of the device's advantages. Sometimes it may be a disadvantage as occasionally a high PIP is needed to inflate a very stiff lung. It may take longer to increase the PIP with a T-piece than with an anaesthetic bag (Bennett et al. 2005). The T_i is determined by how long the outlet is occluded. This may be useful if a sustained inflation is desired. The valve should be occluded for about 0.5 seconds for inflation and open for about 0.5 seconds for expiration. When using a T-piece it is important that the gas flow rate is set (8–10 l/min is satisfactory) and then the PIP and PEEP set. The flow must not be changed during the resuscitation, otherwise the PEEP level will be altered and may become very high (Hawkes et al. 2009).

Pressure or volume during positive-pressure ventilation?

Traditionally in neonatology, pressure has been used as a proxy for the volume delivered during ventilation. Increasingly, however, mechanical ventilators used in NICUs incorporate flow sensors that measure the tidal volume. Many modern ventilators may be set to adjust the PIP automatically to deliver a desired tidal volume (usually 4–6 ml/kg). This volume-targeted approach confers benefit compared with pressure-limited ventilation (Wheeler et al. 2010).

A major limitation of manual ventilation is that the tidal volume is not measured. PPV in the delivery room is pressure-regulated and guided by subjective assessment, which is often inaccurate and frequently causes hypocarbia and hyperoxia in preterm infants (Tracy et al. 2004). A few inflations with a large tidal volume have been shown to cause lung injury in preterm lambs (Bjorklund et al. 1997). Resuscitation guidelines often recommended that initial inflations be given with a set PIP of 20 or 30 cmH₂O; there is, however, little science to support this. Term newborns generate larger negative pressures with their first breaths. The PIP is a very weak proxy for tidal volume. While there is a positive relationship in mannikins – the higher the PIP, the greater the tidal volume – the relationship is weak and highly variable (O'Donnell et al. 2005b). It is likely to be weaker still in babies owing to differences in the severity of lung disease between infants, changing compliance, variable face mask leak and spontaneous breaths. A set PIP cannot be an accurate proxy for an appropriate tidal volume for all babies at all times, especially when they are breathing. There is a mistaken belief that if a set PIP is achieved during mask PPV the leak from the face mask is minimal. In reality, leaks up to 90% may occur and the PIP may still be achieved (O'Donnell et al. 2005b). Achieving a PIP is not evidence of adequate volume delivery because the PIP used may be too low, the leak too large or the airway obstructed.

While clinicians have preferences for manual ventilation devices, no convincing benefit for any type of device has been demonstrated in randomised studies. However, giving respiratory support through an ETT without PEEP is inappropriate. PEEP is always used during ventilation in the NICU and has been shown to halve the oxygen requirements of preterm lambs in the first few minutes of life (Probyn et al. 2004). In studies of newly born preterm rabbits, *te Pas et al. (2009a)* showed the importance of PEEP in forming and maintaining end-expiratory lung volume (FRC) using high-resolution phase contrast X-rays (Fig. 13.7).

Oxygen

Traditionally it was taught that 100% oxygen should be given to infants receiving respiratory support at birth (Kattwinkel et al. 1999). Concerns emerged that high concentrations of oxygen might promote generation of reactive oxygen species which could exacerbate tissue injury, particularly during reperfusion in asphyxiated infants. Experimental animal work was followed by randomised

(Vento et al. 2001, 2003) and quasirandomised (Ramji et al. 1993; Saugstad et al. 1998) trials comparing air to 100% oxygen for resuscitation in term and near-term infants. Meta-analysis of these studies showed significantly reduced mortality in the infants who were initially resuscitated in air (Davis et al. 2004). ILCOR recommendations now state that term infants should be initially resuscitated with air, with oxygen considered for infants who fail to respond to effective ventilation and the use of oxygen guided by pulse oximetry (Perlman et al. 2010).

Preterm infants are more likely than term infants to have lung disease and are at greater risk of hypoxaemia. They also, however, have less well-developed antioxidant defences and so are at greater risk of oxidant injury. Controlled trials in which preterm infants have been randomised to receive higher (90–100%) or lower (21–30%) oxygen concentrations have been reported (Escrig et al. 2008; Wang et al. 2008). These studies were not large enough to measure clinically important outcomes and were designed to see which group achieved predetermined SpO_2 targets better. Most infants randomised to low Fio_2 received supplemental oxygen; however, they

Fig. 13.7 High-resolution (phase contrast) X-rays of ventilated preterm rabbits showing the effect of positive end-expiratory pressure 5 cmH_2O (PEEP) and sustained inflations of 20 seconds (SI) on lung volume. A = SI + PEEP, B = no SI + PEEP, C = no SI + no PEEP, D = SI + no PEEP. (Reproduced from *te Pas et al. (2009b)*.)

had similar SpO_2 after 5 minutes and received less oxygen than those randomised to high FiO_2 . Further studies are in progress. In the meantime preterm infants should start resuscitation with air or 30% oxygen and be monitored with pulse oximetry (Perlman et al. 2010).

The gases delivered to infants in NICU are carefully warmed and humidified to reduce heat loss and to lessen drying and irritation of the airways. The gas delivered in the delivery room is neither warmed nor humidified. *te Pas et al. (2010)* showed a statistically significant 0.5°C difference in temperature on NICU admission among a cohort of preterm infants who received respiratory support with heated and humidified gas. It is not known whether there are other potential benefits, and this deserves further study.

Surfactant treatment

Surfactant therapy was a major advance in the care of preterm infants that reduced mortality from respiratory distress (Ch. 27.2). Randomised trials performed in an era of low antenatal steroid use demonstrated that animal-derived preparations were superior to synthetic ones, and that treatment with higher doses earlier in the infant's course seemed beneficial. More recent randomised trials have compared intubation in the delivery room and early surfactant treatment with starting infants on CPAP and reserving intubation and surfactant for those who go on to develop respiratory failure (Morley et al. 2008; SUPPORT Study Group 2010). These studies showed that these approaches were equivalent, with fewer infants randomised to CPAP being intubated and receiving surfactant and postnatal steroids (SUPPORT Study Group 2010).

Another recent randomised trial study showed that giving prophylactic surfactant to preterm infants on CPAP did not reduce the rate of mechanical ventilation in the first 5 days (Sandri et al. 2010). Preterm infants do not need to be routinely intubated in the delivery room for surfactant; the approach will probably be dictated by local preference and expertise.

Sustained inflation

Sustained (>1 second) inflations have been associated with improved outcomes in preterm babies in a retrospective cohort study and a randomised trial (Lindner et al. 1999; *te Pas and Walther 2007*). The sustained inflation was however only one of several differences in the way that babies were treated, so it is difficult to determine the effect of the sustained inflation alone. A 20-second inflation resulted in greater lung volume in a preterm rabbit model (*te Pas et al. 2009a*). It is a promising technique which deserves further study.

Supporting the circulation

A newborn infant's heart is basically healthy and usually only slows or stops due to hypoxia and acidosis. The initial management is early lung aeration and ventilation. Rarely are the hypoxia and acidosis primarily circulatory problems (e.g. fetal exsanguination or anaemia). Even in these cases respiratory support should be addressed first. The need for circulatory support – chest compressions, adrenaline and volume infusion – is rare. *Wyckoff et al. (2005)* reported that circulatory support was given to 0.06% (23/37972) of infants born at a large US hospital in a 30-month period. As it is a rare event, it is very difficult to study prospectively in a systematic fashion. Therefore, studies of circulatory support in newborns are either retrospective or the information is derived from animal models. Extrapolating from animal studies is difficult as they may not match the human situation; for example, the

commonest model for newborn cardiac arrest is a 2–3-day-old piglet that is hypoxic and hypotensive over a number of hours.

Chest compressions

The primary purpose of chest compressions is to perfuse the heart, thereby increasing oxygen delivery and reducing acidosis. It is recommended that chest compressions should be performed over the lower third of the sternum with two thumbs while the rest of the hands encircle the chest (Perlman et al. 2010). The sternum should be depressed approximately one-third the depth of the chest at a rate of 100 per minute. The recommended ratio of compressions to ventilation is 3:1. This ensures good respiratory support. An end-diastolic blood pressure is needed in the coronary arteries to allow perfusion. Data from a swine model of cardiac arrest demonstrate that end-diastolic pressure is increased by adrenaline and suggest that chest compressions are more effective once adrenaline has been given.

Drugs

Drugs are rarely given at resuscitation (approximately 0.04% of near-term and term deliveries) (*Wyckoff et al. 2005*). If drugs are to be used, it suggests that the infant has severe circulatory compromise but they may often be used because ventilation has been inadequate. In such circumstances drugs need to be given centrally. An umbilical venous catheter may be inserted much more quickly and reliably than a peripheral intravenous (IV) line in an infant with circulatory collapse, and so should always be attempted first. Intraosseous access should be used if IV access cannot be quickly achieved.

Adrenaline (epinephrine)

When an infant does not have a detectable HR or remains bradycardic (HR <60 bpm) despite effective PPV and chest compressions, adrenaline is recommended (Perlman et al. 2010). The use of IV adrenaline has been extrapolated from adult studies, which were based on studies in dogs. ETT administration seems to have evolved based on a report of its use in three newborns (Lindemann 1982). If adrenaline is to have an effect it must reach the heart. It should thus be given through an umbilical venous catheter in a dose of 0.01–0.03 mg/kg (Perlman et al. 2010). If venous access cannot be achieved, then it is reasonable to give adrenaline via the ETT. If given by this route, the dose should be increased (0.05–0.1 mg/kg; Perlman et al. 2010).

Expansion of circulating blood volume

Volume infusion is given to newborns in the delivery room more rarely than adrenaline (*Wyckoff et al. 2005*). Most infants are volume-replete at delivery and extra volume is unlikely to be of benefit. However, occasionally infants have had significant blood loss from fetomaternal haemorrhage or a concealed haemorrhage. This may be very difficult to diagnose but resuscitators should be aware of babies who look very pale and do not respond to adequate ventilation. A bolus of crystalloid usually in a dose of 10–20 ml/kg should be given, and, if the baby is very pale, O-negative blood.

Other drugs

Naloxone, a specific opioid antagonist, has been suggested to reverse respiratory depression in newborns whose mothers received

opiate analgesics in labour. Its use is not based on any data. The priority is ventilation. Naloxone does not help emergency resuscitation and is not recommended (Perlman et al. 2010). There is no evidence that sodium bicarbonate, vasopressors or calcium improve outcomes and they may be harmful so they are not recommended (Perlman et al. 2010).

Meconium-stained liquor

Fetuses pass meconium increasingly frequently with increasing gestational age beyond term (Ch. 12). The passage of meconium in utero may be a sign of fetal hypoxia. When aspirated into the fetal/newborn lung, meconium can cause respiratory problems by a combination of airway occlusion and chemical pneumonitis, which may cause severe parenchymal lung disease complicated by pulmonary hypertension (meconium aspiration syndrome).

Large randomised controlled trials showed no benefit of intrapartum suctioning (Vain et al. 2004), and no benefit of intubation and endotracheal suction of vigorous term infants born through meconium-stained liquor (Wiswell et al. 2000). Though the benefit of intubation and endotracheal suction of non-vigorous infants born through meconium-stained liquor has not been demonstrated, suctioning the airway of an infant who requires ventilation may be useful. It is unlikely, however, to prevent meconium aspiration syndrome as most of the meconium will have been aspirated deep into the lung before birth. Meconium may very rarely block the trachea and require direct suction (see above).

A baby born under general anaesthesia

The majority of CS deliveries are performed under regional anaesthesia. Occasionally, CS deliveries are performed under general anaesthetic. Anaesthetic agents quickly cross the placenta and sedate the newborn. Therefore a person with resuscitation skills needs to be present at all CS deliveries under general anaesthesia.

Congenital anomalies

The wide availability of antenatal ultrasound has led to the increased antenatal detection of anomalies, some of which have implications for the care of the infant at birth. Despite scanning, however, some still present unexpectedly at birth.

Upper airway anomalies

A serious upper airway anomaly encountered soon after birth is the small chin (micrognathia) encountered in the Pierre Robin sequence. This small and sometimes backward-displaced chin can lead to the airway becoming obstructed by the tongue (glossoptosis). In order to relieve the obstruction, the infant should be placed prone. If this is insufficient, a nasopharyngeal airway should be used to bypass the obstruction temporarily. An LMA may be useful in an emergency as intubation can be difficult. See Chapter 27 part 7 for more detail on the management of airway anomalies.

Congenital diaphragmatic hernia

See Chapter 27 part 6. Today congenital diaphragmatic hernia (CDH) is most often diagnosed on antenatal ultrasound, though it

is occasionally still diagnosed postnatally on chest X-ray in term infants with severe respiratory failure. If diagnosed before birth and the decision is made to continue with the pregnancy, the baby should be delivered at term in a tertiary centre. Most practitioners avoid mask ventilation and elect to intubate and mechanically ventilate infants shortly after birth. A wide-bore nasogastric tube is then often placed to decompress the gut.

Gastroschisis (Ch. 29.4)

Infants with gastroschisis or exomphalos rarely have problems during transition requiring resuscitation. The abdomen should be carefully loosely wrapped in polyethylene (food-grade wrap or bag) to reduce fluid and heat loss and surgical assessment should be urgently sought.

Hydrops fetalis

Newborns with hydrops fetalis have severe generalised oedema with accumulation of fluid in the chest and abdomen. They frequently need intubation, which can be difficult if the tissues are very oedematous. They may be difficult to ventilate and need a high PIP to move the chest wall. Thoracocentesis (direct aspiration of fluid from the pleural cavity) may make ventilation easier; this is, however, best performed under controlled conditions in the NICU and should not be considered in the delivery room unless the baby is in extremis. Paracentesis (aspiration of fluid from the abdomen) should not be performed blindly owing to the risk of injury to the liver and spleen, both of which are commonly enlarged in hydropic infants.

Babies still attached to the placenta

Occasionally babies are delivered in intact membranes; these infants are still attached to the placenta. It is important to remember to ligate and divide the cord as the baby may lose a significant amount of its circulating blood volume into the placenta, particularly if it is placed at a lower level than the infant.

Ethics issues

Questions about whether individual babies should be resuscitated and offered intensive care are relatively common. Much of the debate centres on what is 'the threshold of viability' for preterm infants, i.e. at what gestation does the likelihood of survival without disability outweigh the risk of death and survival with disability? Questions as to whether intensive care is appropriate may also arise for infants in whom congenital anomalies are found on antenatal ultrasound or at birth. All decisions must be guided by what is perceived to be in the child's best interests. Applying an institutional policy contrary to parental wishes is undesirable (Annas 2004). While on occasion opinions from independent ethics committees may be helpful, they are rarely available in a timely fashion. The decision should be made by parents in consultation with doctors in each individual case. If time allows, a clear plan to offer intensive care in the hope of intact survival or to offer comfort care in the expectation of death should be made before the baby delivers. Though it is tempting to wait until an extremely preterm baby is born to assess his or her condition, condition at birth does not accurately predict intact survival (Manley et al. 2010). For more discussion on ethics issues, see Chapter 6.

Teaching and training

Formal teaching of neonatal resuscitation techniques is widespread – it is estimated that 2 million people have attended a Neonatal Resuscitation Program (NRP) course in the USA alone (http://www.aap.org/nrp/intl/intl_abroad.html) – and is mandatory for training in paediatrics in many countries. While teaching the NRP has been demonstrated to improve Apgar scores in certain jurisdictions and leads to increased confidence among caregivers, it is disappointing that the introduction of widespread training in neonatal resuscitation did not reduce infant mortality in an area with high infant mortality (Carlo et al. 2010). Training has traditionally been didactic and mannikin-based. However, there are difficulties with this approach – knowledge deteriorates with time, it is difficult to acquire and maintain physical skills in this manner and there are serious concerns about how life-like the experience is. To address these issues there is increasing interest in simulation, which aims to give a more life-like experience in a controlled environment.

Research in neonatal resuscitation

Resuscitation of infants at birth has been the subject of many articles. Seldom have there been such imaginative ideas, such enthusiasms, and dislikes, and such unscientific observations and study about one *clinical picture*. There are outstanding exceptions to these statements, but the poor quality and lack of precise data of the majority of papers concerned with infant resuscitation are interesting (Apgar 1953).

The methods used to support transition and resuscitation of newborns have, until relatively recently, been subjected to little systematic study and very little in the way of randomised studies. There are likely to be many reasons for this. The need for resuscitation often arises with little or no warning. Babies cannot themselves consent to participate in research studies; instead, this decision falls to their parents. Resuscitation of a newborn is always a stressful event, in particular for families, but also for the nursing and medical

staff caring for the baby and the mother. It is difficult for caregivers to acknowledge uncertainty in such situations. These factors conspire to make it difficult for caregivers to obtain prospective informed consent from stressed parents to enrol infants in studies in a short time. People correctly debate the ethics of doing research in infants who cannot give consent for themselves.

Unfortunately, the ethics of not doing research in such infants is less frequently debated. Before a new medication or device is approved for use in adults, it must be subjected to detailed studies in large numbers of adults to determine clearly that it has beneficial effects which outweigh any unwanted harmful effects. Discouraging research in babies makes it more difficult to determine that the interventions used to treat them work and are safe. This implies that a lesser standard of proof than that required for the treatment of adults is acceptable for babies. This approach is misguided, dangerous for babies and potentially infringes their human rights.

It is difficult to obtain prospective informed consent for studies of emergency interventions in all age groups; consequently, many commonly used, invasive and potentially life-saving emergency treatments are poorly studied in humans. To address these difficulties, different approaches, such as the use of deferred consent or a 'waiver of informed consent', have been used to enrol patients in studies of emergency interventions. In circumstances where it may not be possible to obtain consent prospectively, a research ethics committee may allow for patients to be enrolled without prior consent. Subsequently either the patients themselves or their next of kin or guardian are informed that they have been enrolled and their consent is sought for continued participation in the study. These have given valuable information about care of newborns and adults that has changed clinical practice. There are many areas of uncertainty in neonatal resuscitation – for example, the roles of monitoring (pulse oximetry and flow sensors), titrated oxygen, delayed cord clamping, nasal airways. These and other topics are subject to ongoing studies, including randomised clinical trials. It is critical that this research is supported, as the results of these studies will inform the body of evidence that already exists and will enable us to improve and refine the care of vulnerable newborns.

Part 2: Neonatal transport

Steve Kempley Nandiran Ratnavel

Transport is a vital component of any network of hospitals serving a neonatal population. Although retrieval of babies into specialist centres has been practised for over 50 years, dedicated and efficient teams able to deal with both retrieval and return are a very recent development in the National Health Service. Earlier services involved ad hoc arrangements with equipment which was adapted and secured using a variety of locally inspired methods. Retrieval

was often delegated to the most junior member of the team. It is now recognised that reliable and safe equipment and vehicles are essential, not a luxury, and staff benefit from specific training and experience. Despite enormous improvements in this respect, flexibility and quick thinking remain an essential attribute for staff involved in this challenging area of neonatal medicine (Fig. 13.8).

Fig. 13.8 The process of neonatal transport.

Remit of neonatal transport

Most neonatal transport services provide for any baby moving between neonatal units, although not all are 'neonates' using a strict definition (many are older than 28 days).

The requirement for neonatal transport depends on the organisation of maternity, neonatal and specialist services. In a densely populated area of the UK with large maternity units, interhospital neonatal transfers were needed for 9 per 1000 live births, of which 4–5 per 1000 were for urgent transfers of sick babies (Kempley et al. 2007). The commonest reasons for urgent transfer were medical intensive care (39%), surgery (31%), cardiac (17%) or other specialist care. However, in areas with many local, small maternity units, up to 10% of newborn babies may require transfer (Branger et al. 1994). Services must decide whether to cater only for interhospital transfer, or whether to retrieve babies from home and midwifery unit births, which may reach hospital faster using local paramedic ambulance services.

Clinical and physiological stresses and pretransport stabilisation

The clinical condition precipitating transfer may cause significant physiological dysfunction, to which will be added the effects of the transfer. Motion, vibration, noise and seasonal temperature fluctuations all act to destabilise the baby's condition (Barry and Leslie 2003). Pretransport stabilisation anticipates these effects; one should aim to optimise the infant's condition in advance rather than simply maintaining the status quo. The baby's stability should be assessed systematically, evaluating respiratory, cardiovascular, gastrointestinal, renal, metabolic, neurological, septic, haematological and biochemical parameters as well as checking fluid status and the adequacy of vascular access. The aim is to optimise the patient's ability to tolerate the transport episode.

Particular care must be taken with temperature management in premature or low-birthweight infants. The effects of skin

immaturity and high surface area will be magnified by transport-specific effects such as limited incubator performance, use of unwarmed or non-humidified ventilator gases and exposure to outside environmental temperatures. Keeping a patient in the thermoneutral zone will avoid the effects of hypothermia, which increases oxygen requirement, impairs surfactant production and renders metabolic processes less efficient. Measures during stabilisation which reduce thermal stress (Advanced Life Support Group 2008) include minimising exposure for procedures, using incubator portholes, prewarming the ambulance, nursing in a prewarmed incubator and ventilation using warmed, humidified gases. The infant should wear a hat and temperature should be continuously monitored. We do not advise attempting to transfer the baby unless central temperature is at least 36.5°C. A baby that starts a journey cold will be difficult to warm up en route.

Clinical care during transport

The patient and transport equipment must be prepared and packaged prior to leaving the referring unit, with a formal checklist used for final checks of physiology and utilised equipment. A telephone call to the receiving unit gives an overview of the patient's condition, the ventilator and infusion settings and estimated time of arrival.

Once moving through the hospital the incubator system will be dependent on its own power and gases. There should be a recognised loading system into the ambulance which does not expose staff to manual handling risks and a procedure for fixation of the equipment system within the vehicle. Once in the vehicle, equipment should be connected to ambulance supplies of gas and power, to preserve those on the transport rig.

Patient monitoring must be maintained through this process and the journey. In addition to standard parameters (heart rate, oxygen saturation, blood pressure and temperature), continuous end-tidal carbon dioxide (EtCO₂) measurement can rapidly identify ventilation failure from endotracheal tube blockage, displacement or

equipment failure. Sidestream EtCO₂ sampling adds little dead space; although the absolute measurement differs from arterial values, we find the qualitative waveforms very useful in a transport setting. Given the vulnerability of monitoring systems to vibration artefact, an unrestricted view of the baby is needed to assess colour, chest movement and pain.

Although incidents are minimised by pretransfer stabilisation, staff must have a rapid troubleshooting approach to solving problems. Seating should give a good vantage point to confirm that ventilator pressures are being delivered, that gas supplies are adequate, that ventilator tubing is neither disconnected nor compressed and that capnograph waveforms indicate ongoing ventilation. This can all be achieved without unfastening seatbelts. If closer inspection is needed, the ambulance should stop at the first safe opportunity; only then should staff disengage their own restraints. The majority of incidents can be readily resolved with simple adjustment of ventilation, infusions or endotracheal suction. All emergency equipment and drugs should be kept close to hand to deal with much rarer emergencies such as displaced tubes, pneumothorax or cardiac arrest.

Care at receiving hospital

On arrival in the receiving unit transport equipment must be plugged into the hospital gas and power supplies and local decontamination procedures observed. A good handover is the basis to successful ongoing management of the patient; key individuals should be identified and an efficient dialogue facilitated, with relevant staff having the opportunity to clarify information. Documentation, imaging and test results should be reviewed and the receiving unit's questions answered.

Movement of the baby from transport to unit incubator is frequently the point at which good patient preparation comes undone. Good practice ensures that all tubes and lines are secure, infusion syringes are transferred across with a minimum break in drug delivery and that lines are gathered up to prevent them becoming snagged or tangled. Tasks should be clearly delegated; following transfer the infant should be examined to ensure he or she is still being ventilated and that all tubes and lines are still in place. Only then does responsibility for the patient pass to the receiving unit staff.

Communication

Concise and efficient communication skills are required at all stages of the transfer process. This begins with an unambiguous referral to the transport service which identifies the patient, the referrer and hospital. A succinct 'sound bite' to introduce the infant's problems and to establish the need for transfer sets the scene for the subsequent referral. The transport service needs a streamlined process for collecting relevant clinical details at the initial telephone referral, encouraging important aspects of treatment to be established prior to the team's arrival.

The next level involves defining the patient's current treatment and how he or she has responded. This shapes advice given to the referring unit before the transfer team arrives. Communication failure at any stage of the transfer is associated with adverse events (Lim and Ratnavel 2008). Transport coordinators provide an interface between different agencies and need to ensure unimpeded communication with all relevant parties and collation of their input.

In addition to clinical advice, there will be a need for bed location, liaison with the receiving unit, the network centre and possibly other transfer teams. All conversations require dated and timed documentation. Many services need separate requests to the ambulance service, which needs to define the correct vehicle type. At all stages sympathetic and supportive advice to the parents will need to be maintained.

Organisation of services

Well-organised neonatal transport services must deliver appropriate clinical care with minimal delays. Critical elements include a reliable telephone contact point, specialist equipment, systems for rapidly assembling a full team, rapid access to an appropriate vehicle or aircraft and a cot-finding system. Centrally organised, integrated teams can despatch a team to a baby within 20–30 minutes, without delaying to find a cot or an ambulance, but such services involve expenses which must be justified by high usage levels. Based on rates of transfer and journey distances in England, a birth population of 80 000 per annum may be needed to justify a 24-hour neonatal transport team performing an average of two transfers per day.

Less densely populated areas may generate longer duration transfers and may need different arrangements, such as on-call teams which can be rapidly mobilised. An alternative model may involve teams which transfer both neonatal and paediatric intensive care unit (PICU) patients. Unfortunately, many healthcare systems lack medical and nursing training structures which develop high-level skills in both neonatology and PICU. The future evolution of a subspecialty of transport medicine may improve the ability of teams to cover both types of transfer.

Even with dedicated vehicles, teams will periodically require the assistance of other emergency services, so close liaison is required with local ambulance services.

Staffing

The traditional neonatal transport team consisted of a neonatal doctor and nurse, with an ambulance team who drove the vehicle. This model is progressively being replaced by integrated teams whose roles are based on competencies rather than professional designations. Neonatal transports are now being led by nurse practitioners, paramedic practitioners, nurses and doctors trained in neonatal transport.

Training

Specific neonatal transport training now constitutes part of the subspecialty training in neonatology, recognising that unit-based practice is not necessarily transferable to the transport environment. As well as clinical aspects, training involves communication skills, triage, problem-solving, equipment familiarisation and knowledge of the transport environment.

Introduction of approved transport competencies into the workplace has promoted generic competency training across professions. In addition, there are some discipline-specific competencies combining knowledge-based items and procedural/equipment competencies. With a more fluid approach to clinical work and the use of equipment, all staff members have familiarity with each other's roles and can assist more easily when circumstances are pressing. In this model it is mandatory to teach and assess the relevant competencies in a clear and structured way.

Governance

Neonatal transport is a high-risk area with the potential for adverse events, requiring a proactive approach to risk management and robust governance procedures (Ratnavel 2009). Regular case debriefs focus learning on team performance both clinically and operationally. Transport services should have their own incident-reporting system with cross-organisational mechanisms for review and feedback. Risk management structures need clear terms of reference and guidelines on criteria for serious untoward incident investigation, which must feed into the hosting organisation's reporting system. Relevant incidents should also be reported to the National Patient Safety Agency via the National Reporting and Learning System to allow a national picture of common events to be formed. This is also useful benchmarking between teams and national reviews of neonatal transfer services.

Equipment and vehicles

Equipment should only be taken on transfers if it performs an essential function. This will include a means of keeping the baby warm (usually a transport incubator), monitoring, respiratory support (including mechanical ventilation and continuous positive airway pressure), a suction system, infusion pumps, disposable items and possibly a nitric oxide system. The most important differences between equipment used on neonatal units and that used in transport are the need to minimise weight, whilst ensuring the equipment can function independently of external power sources. Transport incubator systems often lack the sophistication of unit-based equipment, but simple incubators can be supplemented by the use of active warming devices such as acetate gel mattresses.

Fixation of patient, staff, equipment and all other items in the vehicle is a basic safety requirement. All equipment, from the incubator to the syringe drivers, must be fixed to ensure they do not become lethal missiles in the event of a vehicle collision. There are different requirements for land-based and air transport which provide an absolute minimum safety standard (BS EN 13976-1 and 13718-2). Staff should be seated and secured throughout the journey; rearward-facing is safest but forward-facing reduces motion sickness. Fixation systems are now available to secure the baby safely within the incubator; the Neo-Restraint uses conformable foam wedges to prevent mass movement without causing direct pressure on delicate neonatal skin.

Dedicated neonatal vehicles provide a number of advantages over front-line ambulances. The weight of the incubator system can be markedly reduced through provision of AC power and compressed gases in the vehicle, although some independent supply will be needed for movement to or from the vehicle and to cope with emergencies (Kempley et al. 2009). Additional equipment such as a cold light source and a bigger supply of consumables can be easily accommodated on dedicated vehicles.

Air transport

Air transport is required for either long-distance transfers or to deal with local geographical issues such as islands or adverse road conditions. There are challenges involving organisation, equipment, communication, physical conditions and staff training. Air transfer often needs to link with road transfer for direct access to any hospital that does not have a landing site, needing prior plans for the compatibility of equipment in the ambulance and the aircraft. Transport services with an established airborne facility usually have a volume of work, making it reasonably cost-effective. Development of such services requires liaison between clinicians, aviation operators, ambulance managers, medical physics technicians and engineers (Skeoch et al. 2005). Ad hoc air transfers are expensive and run the risk of staff being unfamiliar with both equipment and environment.

Equipment should include the normal elements with automated loading and fully integrated gas supplies. It should be able to withstand frequent movement and vibration. Layout should allow the clinician good visibility and access; visual alarms are preferable to audio systems. Stress and electrical installation reports must be approved by the appropriate aviation safety agency. Aircraft-specific compatibility tests then need to be carried out and a servicing agreement needs to be in place.

For staff safety, clothing should be weatherproof, high-visibility and flame-retardant, with head and hearing protection provided. As air transfer increases the risk to patients and staff above and beyond the increased risk associated with road transfer, adequate insurance cover must be provided.

Air transfer imposes particular clinical considerations. Altitude reduces the partial pressure of oxygen, leading to a reduction in the infant's oxygen saturation, so that oxygen delivery may need to be increased. Expansion of gas with increasing altitude means that a small pneumothorax may expand to become dangerous; even small ones should be drained prior to transfer.

Parents

Careful consideration must be given to parents already facing distress over their baby's illness. A short detour to the labour ward may be worthwhile to allow the mother to see the baby before transfer. Parents should be given a photograph of the baby and clear directions to the destination unit. The dangerous situation where parents chase the ambulance in their own car must be avoided.

For elective journeys, parents can often accompany the baby. For acute transfers, the number of staff in the ambulance and other safety factors should be assessed. It may be unsafe to transfer a mother in a neonatal ambulance immediately after caesarean section or following intrapartum haemorrhage. Flexibility is needed; some parents prefer to stay together in the referring hospital, others prefer a parent to accompany the baby, especially if urgent surgery is imminent. An ambulance, taxi or other safe transport should be arranged for parents who follow their baby later.

Introduction

A thorough physical examination of every neonate has long been accepted as good practice and forms a core item of the child health surveillance programme in many countries (Hall and Elliman 2003; NICE 2006). There are now agreed standards for the conduct of this examination, which forms part of the National Health Service screening programme in the UK (see [Weblinks](#)). The Newborn and Infant Physical Examination (NIPE) programme has clearly defined goals, target conditions and competency standards. The four current target conditions are hips, eyes, heart and testes. The first detailed examination should take place within 72 hours of birth and the second at 6–8 weeks. The mother should have been given information about the NIPE programme during pregnancy, and consent should be obtained. Non-consent must be recorded and followed up, and notified to the appropriate child health information department.

The aims of the routine newborn examination are:

- to review any problems arising or suspected from antenatal screening, family history or the events of labour
- to ascertain whether the family have any worries about the baby and to try to address them
- to initiate appropriate treatment and arrange for advice and follow-up where indicated (e.g. hepatitis vaccination, phototherapy for jaundice, special teat for cleft palate)
- to screen for specific target conditions, currently developmental dysplasia of the hip (DDH), cataract, undescended testes and congenital heart disease
- to diagnose congenital malformations and common neonatal problems, and give advice about management

- to detect the occasional baby who is obviously ill and requires urgent treatment
- to collect baseline information about weight and head circumference, and to check that the baby has passed urine and meconium
- to identify parents who may have problems in caring for their baby because of substance abuse, mental health problems, learning difficulties or very poor housing and to alert the appropriate professional groups
- to begin to provide health education advice, e.g. regarding breastfeeding, cot death prevention, safe transport in cars.

For some babies, early diagnosis may make all the difference to their subsequent health; examples are congenital cataract and urethral valves. For others, reassurance about minor deviations from normal (birthmarks, syndactyly of the toes, extra digits) is all that is required. The slightest variation from what the family consider to be normal may produce the most intense distress and anxiety at a stage when the mother is emotionally very labile.

The yield of abnormal findings is surprisingly high, with up to 20% of healthy newborns being found to have one minor anomaly (Adam and Hudgins 2003). Most of these are of no importance, although the number of such abnormalities matters (Table 14.1).

Table 14.1 Common minor neonatal abnormalities and their importance

Abnormalities that do not matter when isolated (three or more such abnormalities do matter)

Folded-over ears
Hyperextensibility of thumbs
Syndactyly of the second and third toes
Single palmar crease
Polydactyly, especially if familial
Umbilical hernia, especially in Afro-Caribbean babies
Single umbilical artery
Hydrocele
Fifth-finger clinodactyly
Simple dimple just above the natal cleft (see text for definition)
Undescended testes
Single café-au-lait spot
Single ash-leaf macule
Third fontanelle (5% of babies)
Capillary or strawberry haemangioma
Accessory nipples

Abnormalities that might matter even when they are isolated

Ear pits and tags
More than three café-au-lait spots in a Caucasian baby, more than five in black African babies
Multiple haemangiomas, or strawberry haemangiomas in specific places (e.g. ophthalmic division of the trigeminal nerve in Sturge-Weber syndrome, or in the midline over the spine)
Oedema of the feet – think of Turner syndrome
Asymmetric crying facies
Microcephaly
Macrocephaly
Micrognathia
Midline skin defects over the spine other than simple dimples
Scrotal swelling/discoloration (think of torsion of the testes)

Only 0.5% of babies have three such anomalies, and the risk of an accompanying major malformation then rises from 3% (with one minor anomaly) to 20%. Unfortunately, the examination is not a reliable screen for several important conditions such as DDH, cataract and congenital heart disease (see below).

Who should examine the baby?

Babies should be examined by a trained practitioner who has the time to talk and listen to the mother. In the past, all neonatal examinations were carried out by paediatricians, usually junior paediatricians with some specific basic training. Generations of paediatric residents have learnt the range of normality by performing large numbers of 'baby checks', and they have the advantage of a full medical training and a direct chain of referral. Recently, advanced neonatal nurse practitioners and trained midwives have begun to undertake the examination, and mothers are usually very satisfied with the service they provide (Lee et al. 2001; Wolke et al. 2002). In a randomised trial conducted in south-east England (Wolke et al. 2002), mothers whose baby was examined by a midwife were more satisfied than the group whose baby was examined by a paediatric senior house officer (SHO), although the general level of satisfaction was very high. The reason why the midwives' examination was preferred was that there was more provision of health education advice (related to feeding, sleeping and skin care). Once this was controlled for, the differences in satisfaction disappeared. The midwives took 5 minutes longer, on average, to conduct the examination than the SHOs. Randomisation only took place during the working day, and half of all babies born during the study period were excluded from randomisation because of problems such as maternal disease, low birthweight, operative delivery or a need for resuscitation at birth.

When should babies be examined?

Many babies are currently discharged home before 8 hours of age. The advice from the NIPE programme is that there is no optimal time to detect all abnormalities, and it is considered that the overall risk associated with babies going unscreened is greater than if babies are examined early. Hence, the conclusion is that all babies should be offered the examination before discharge even if this is at or before 6 hours. The logistics of delivering a high-quality screening examination on this timescale can be formidable in a busy maternity service, and a back-up arrangement such as a walk-in clinic or community liaison is essential to make sure that all babies are examined before 72 hours.

Examination in the delivery room

All babies should be checked soon after birth; this will generally be done by the midwife following uncomplicated full-term labour, but if the paediatrician has been called to the delivery she should make a quick appraisal of the infant after any necessary resuscitation. This examination is usually confined to ensuring that the infant looks well and that there are no major abnormalities requiring immediate attention or explanation to the parents such as hare lip/cleft palate, spina bifida, anal atresia or ambiguous genitalia. This is a most sensitive and important time for parents and they should be given the opportunity to be left alone with their baby as soon as possible. This check is not, and should not be, the full examination which forms the first NIPE screening examination.

Full routine examination

Mothers meticulously inspect their own babies, hence one of the most important functions of the examination is to answer any questions which the mother may raise. It follows that the examination should, if possible, always be done in her presence. The following general format is recommended:

1. Check the maternal medical, obstetric and social history from the notes, the mother and the nursing staff.
2. Introduce yourself to the mother with an explanation about what you are doing.
3. Fully examine the baby.
4. Give advice and information, arrange follow-up and provide reassurance where appropriate. When giving advice, remember that the neonatal examination is not a perfect screening tool.

History and background knowledge

Before approaching the mother and infant, read the baby notes to obtain basic information about the mother's previous obstetric and medical history as well as the type of delivery and the baby's condition at birth; note also the birthweight, gestational age and sex. If there are complicated medical or social problems it is helpful to discuss them with the nursing staff beforehand and also to check the mother's notes for details.

It is useful to have a mental checklist of relevant background information to obtain before starting the examination. This should include:

- The baby's sex.
- The baby's birthweight and reputed gestational age and whether these are mutually compatible.
- The mother's age and social background.
- Is there any chronic maternal disease? If so, what treatment is the mother receiving?
- Is there a history of recreational drug and/or alcohol use? Is the mother a smoker?
- Is there any possibly relevant family history?
- The outcome and dates of any previous pregnancies.
- Was the pregnancy normal? Were there any complications?
- What were the results of pregnancy screening tests, e.g. 20-week ultrasound scan?
- Were any special diagnostic procedures, e.g. amniocentesis, performed?
- Were there any signs of fetal compromise during labour?
- What drugs and/or anaesthesia were given during labour and delivery?
- How was the baby delivered?
- Was there a breech presentation after 36 weeks (an indication for a hip scan)?
- What was baby's condition at birth (Apgar scores at 1 and 5 minutes, cord pH)?
- Was any resuscitation needed?
- How long before sustained respiration was established?
- Was the baby in the neonatal unit? If so, why?
- How is the mother planning to feed the baby, and how is the feeding going?

Introductions and general 'gestalt' inspection

The doctor should introduce herself and say what she has come for. To ask the baby's name and record it helps to establish a good relationship. So many early worries are concerned with feeding that one should always enquire what method the mother is using and

whether she is happy with it. Routine weighing and feed charts have been abandoned in most UK maternity units, but the incidence of readmission with hypernatraemic dehydration due to breast milk insufficiency has risen (Laing and Wong 2002). All babies lose weight after birth, 2–3% each day to a maximum of around 10%, but it is rare for a baby to lose more weight than this, or to remain more than 10% below birthweight after the 5th day (Wright and Parkinson 2004). If there is a current weight, then a quick calculation of weight lost or gained since birth should be made.

Enquire about the health of any previous children. There may have been previous stillbirths, infant deaths or adverse outcomes about which the mother may be extremely anxious. The examiner should also review and confirm any relevant items of background information gleaned from the notes. Always ask the mother whether she has any specific worries, when she is expecting to be discharged and what support she has at home. Knowledge of the father's and mother's occupation provides useful background information. By means of these preliminary pleasantries one can usually quickly establish a relationship and can gauge the level at which to discuss any problems. During these introductory minutes the examiner can try to make the mother and her partner (if present) feel like individuals, and can also do two other very important things:

1. observe the mother's attitude to her baby, and whether she is confident and happy or tense and withdrawn
2. observe the baby, noting colour, facies, breathing pattern, posture and movements.

An enormous amount can be learned by these simple observations while continuing to chat to the mother. For recording purposes it is useful to have a checklist printed or stamped in the baby's notes to serve as an aide-memoire. The examination must be appropriately documented; increasingly this involves a computerised record. The experienced observer uses 'gestalt' to assess the importance of minor dysmorphic features (Table 14.1), subtle signs of illness, or atypical behaviour patterns.

Formal examination

The baby must be undressed down to the nappy for most of the examination time; it is impossible to examine a clothed baby properly. Most parts of the examination can be performed in any behavioural state, and the order in which this is done is largely a matter of personal preference, but working from top to toe down the front and vice versa up the back is as good as any other. Full advantage should be taken of any quiet or sleeping periods to feel the anterior fontanelle, look at the eyes, auscultate the heart and palpate the abdomen. It is wise to leave the hips until nearly the end of the examination, even though this item is arguably one of the most important items on the agenda and must be done with the infant quiet and relaxed, because the Ortolani-Barlow test often makes the baby cry. Throughout the whole examination one is at first consciously, later almost subconsciously, observing such things as posture, muscle tone, movements and reaction to stimuli so that finally there is very little need for a formal evaluation of the central nervous system unless suspicious signs have come to light. A suggested order for the examination is as follows; details of what one is looking for are given in the systematic review.

Order of examination

- Remove the baby's clothes except the nappy.
- Feel the anterior fontanelle for tension (leave until later if the baby is crying!).
- Look at the face for colour or any peculiarities.

- Listen to the heart and estimate heart rate and respiratory rate. The lungs can also be auscultated but this is seldom informative.
- Palpate the abdomen.
- Return to the head and examine scalp and skull and measure head circumference and record it, together with the weight.
- Examine the eyes, ears, nose and mouth.
- Examine the neck, including the clavicles.
- Examine the arms, hands, legs and feet.
- Remove the nappy.
- Feel for the femoral pulses.
- Examine the genitalia and anus.
- Turn the baby to the prone position and examine the back and spine, and assess tone.
- Return the infant to the supine position and evaluate the central nervous system.
- Examine the hips.
- Make sure you have not omitted anything and check you have paid attention to any concerns expressed by the mother.

Systematic review

Skin

During the general examination the colour and texture of the skin should be noted as well as any birthmarks or rashes. Birthmarks are common in babies, and most are vascular or pigmentary lesions (Hernandez and Morelli 2003). Many are normal variants, but some are of great importance. Sturge-Weber syndrome occurs in 10% of those who have a port wine stain involving the ophthalmic division of the trigeminal nerve, for example.

The frequency of café-au-lait spots varies tremendously and it is common to see one spot, although more than three are rare. Some have recommended that any Caucasian baby with more than three such spots, and any African baby with more than five, be followed for the development of multisystem disease (Landau and Krafchik 1999). Many other skin lesions are described in Chapter 32, and some excellent illustrated textbooks are available (Eichenfield et al. 2008).

Skin colour

Healthy warm Caucasian babies should be reddish pink all over after the first few hours of life, but they can be covered with white cheesy vernix; this can also be stained a golden yellow in post-maturity or appear greenish if meconium has been passed before birth.

Cyanosis

Cyanosis is usually discernible when arterial blood is 80% saturated, but the ability to detect cyanosis varies between individuals and with different lighting conditions. Cyanosis can be difficult to evaluate in an infant who is very pale (anaemic or peripherally shut down) or racially pigmented. Plethoric infants (central packed-cell volume >65%) can appear cyanosed because they have more than 5 g of reduced haemoglobin per 100 ml even when adequately oxygenated. Peripheral cyanosis of the hands and feet and circumoral cyanosis (acrocyanosis) are common during the first 48 hours. It is essential to ascertain that cyanosis is not central by noting whether the tongue is blue. Traumatic cyanosis or bruising of the presenting part, sometimes associated with petechiae, is also quite common, particularly over the face if there has been a nuchal cord. If there is any doubt check arterial oxygen saturation with a pulse oximeter. Babies with confirmed central cyanosis should be

admitted to the neonatal unit and investigated urgently, beginning with a blood gas estimation and a chest X-ray and proceeding to an early echocardiogram if there is no evidence of respiratory disease.

Cyanosis during crying early in postnatal life may be quite normal as a result of transient elevation of pulmonary vascular resistance with right-to-left shunting, but cyanotic attacks should always be taken seriously.

Pallor

Mature babies appear paler than preterm ones, because of their relatively thick skin. Generalised pallor may indicate anaemia, peripheral shutdown with shock, or both. The capillary filling time can be estimated by pressing on the skin and should not be longer than 3 seconds if the skin is warm.

Jaundice

This is discussed in detail elsewhere (Ch. 29.1) but is often detected first during the routine newborn examination. Icterus appearing in the first 24 hours requires urgent investigation and treatment and should at once evoke the response 'What is the mother's Rh and ABO group? Were there any antibodies and are there any other signs of congenital infection?'

Jaundice appearing between 2 and 4 days is extremely common. Jaundice in preterm (including near-term) babies requires very careful evaluation and if any jaundiced baby is ill in any way (unduly lethargic, feeding poorly, vomiting or has an unstable temperature), infection – or worse, bilirubin encephalopathy – must be excluded. The level of bilirubin is hard to judge by eye, and hence it must be measured. A transcutaneous bilirubinometer can be used (Ch. 29.1). This is particularly important in Afro-Caribbean, Oriental and Asian babies in whom clinical assessment of jaundice is fraught with hazard. Healthy term infants are not immune from kernicterus but levels of bilirubin above 500 µmol/l are probably required to produce it (Ch. 29.1). Audits have shown that common factors are lack of professional concern about jaundice, inadequate breastfeeding and a failure to recognise that the near-term baby (35–37 weeks) is particularly susceptible. These risk factors have been recognised by the National Institute for Health and Clinical Excellence (NICE), together with a family history of a sibling requiring treatment for neonatal jaundice. All babies with risk factors should be examined at around 48 hours to assess whether visible jaundice is present.

Skin texture

Note whether the skin is peeling (common in postterm infants), nice and firm (normal) or very loose (intrauterine growth retardation or dehydration). Oedema is uncommon in full-term infants and should always raise the question of hypoalbuminaemia. Pedal oedema and a low hairline should make the examiner think of Turner syndrome in a baby girl (Ch. 31).

Skin rashes

These are very common in newborn babies. Flat lesions are described as macular (by definition macules are <1 cm but the term is not always used this way). Raised lesions are described as papular when they are up to 1 cm in size and nodular up to 2 cm. Raised clear fluid-filled lesions are vesicular (<1 cm) or bullous (>1 cm). When raised lesions contain purulent fluid they are termed pustular. Diagnosis of a petechial rash, which does not blanch on pressure, should prompt a platelet count. Milia are tiny cream papules, which are inclusion cysts containing trapped keratinised stratum corneum, and which usually resolve without treatment.

The most frequent skin disorder of newborn infants is erythema toxicum neonatorum (toxic erythema; [Ch. 32](#)). There is an eosinophilic infiltrate into the dermis and there can be an associated eosinophilia in the blood. The rash usually starts between 24 and 48 hours of age and resolves by the fifth day. The appearance has been compared to a flea bite.

Transient neonatal pustular melanosis ([Ch. 32](#)) is extremely common in Afro-Caribbean babies, and is a similar reaction to erythema toxicum although the lesions are present from birth. These pustules contain neutrophils. The pustules are very fragile and easily wiped away to leave a scaly area. This area resolves into hyperpigmented brown macules. They have been termed lentigines because of their resemblance to lentils, but they are not true lentigines. The macules last for several months before fading. No treatment is needed and the main importance of recognising the condition is to avoid overtreatment on the basis that they are thought to be due to a staphylococcal infection.

Milia are papules that commonly appear on the face or scalp, although they can occur anywhere, including on the penis and inside the mouth (where they are called Epstein's pearls when they are found on the palate). They are tiny white smooth-surfaced papules. They are inclusion cysts which contain trapped keratinized stratum corneum. They usually clear up within a few months and no action other than reassurance is necessary.

Miliaria rubra, or prickly heat, is common in hot humid climates. The rash usually occurs mainly on the head and upper trunk.

Head and skull

Babies' heads can be considerably distorted and moulded during labour and delivery; there may be a marked caput succedaneum (oedema caused by pressure over the presenting part) which subsides in 2–3 days, or the soft skull bones can be greatly moulded. Either or both of these factors can produce bizarre head shapes which persist for the first few days and sometimes longer. It is important to distinguish deformation – the result of impact from mechanical forces on normal tissue – from malformation. Up to 20% of babies show effects of intrauterine constraint ([Graham 1994](#)). Babies who have been in the breech presentation for a long time in utero often have a 'breech head' with a prominent occipital shelf ([Dunn 1976](#)).

Feel the anterior fontanelle for its tension and size; it can measure up to 3 × 3 cm at its widest points, though the size is very variable. Fullness may indicate raised intracranial pressure (cerebral oedema, hydrocephalus or meningitis). The posterior fontanelle is often open at this age but is usually only fingertip size, with only 3% more than 2 cm in diameter. Examine the cranial sutures for any undue separation, which is abnormal. Overriding of the bones of the vault is common in the first 48 hours, but ridging at the suture lines, as opposed to the 'step-up' feel of overriding, implies craniosynostosis (premature fusion of the sutures). The sagittal suture is the most commonly affected. Craniosynostosis occurs in about 0.4 per 1000 births and may require a neurosurgical procedure for cosmetic correction, or to allow brain growth if several sutures are fused ([Hunter and Rudd 1977](#)). Limb defects, particularly syndactyly, are the most common associated malformations and it may be worth asking the parents if they have fused toes.

Palpate the skull bones; small areas of craniotabes caused by pressure from the maternal pelvis occur in 2% of normal newborns and are of no significance ([Graham and Smith 1979](#)). Cephalohaematomas – collections of blood between the periosteum and the skull bones – are felt as softish bumps over the affected bone, most commonly the parietal, and do not extend across the suture lines. Explain their benign nature to the mother and add that they may

take 6 weeks or more to subside. A boggy swelling crossing a suture line is more sinister and can indicate subgaleal haemorrhage ([Ch. 40.3](#)). There may be a chignon from the use of a vacuum extractor. Neonatal skull fractures are rare. Elevation of the 'ping-pong' ball type of fracture where the bone is depressed but not fractured can be achieved with the application of a vacuum extractor. Linear skull fractures usually require no treatment but should be followed with a repeat X-ray because if the dura has been torn a 'growing' fracture can develop ([Rothman et al. 1976](#); [Scarfo et al. 1989](#)).

Inspect the scalp for any injury such as forceps marks or lacerations from scalp electrodes, fetal blood sampling or instrumental delivery. Look also for any bald patches or naevi over the scalp. A small defect of the scalp, cutis aplasia, can be confused with the scar of a scalp clip electrode. Cutis aplasia ([Ch. 32](#)) is a serious congenital abnormality with a risk of infection and bleeding from the underlying dural venous sinuses, and may be a clue to an underlying diagnosis such as Adams–Oliver syndrome.

Measure the occipitofrontal head circumference (OFC) at its maximum and ensure that it falls within the normal range (approximately 33–37 cm at term). Compare the measurement with any pre-existing measurements; rapid enlargement of the head after birth with boggy swelling crossing the suture lines is due to the rare and dangerous condition of subgaleal haemorrhage ([Ch. 40.3](#)). There is a strong association with ventouse delivery. If the head is unduly small (below the second centile) consider dysmorphic syndromes, congenital infections or isolated microcephaly. If the head is unduly large from the beginning consider familial megalencephaly or hydrocephalus. A large head in the presence of widely separated sutures or a full fontanelle requires immediate ultrasound evaluation. Remember that moulding of the skull can lead to an erroneous OFC measurement which returns to normal once the moulding has subsided.

Face

Most babies' faces are unremarkable, apart from perhaps resembling one or other parent. Occasionally, however, the facial appearance is the first clue to an underlying disorder such as Down syndrome. The bloated cherubic face of infants born to mothers with diabetes is also characteristic ([Ch. 22](#)). If unusual facial features are seen this should prompt a particularly diligent search for other dysmorphic manifestations, but if the baby is asymptomatic and otherwise normal the appearance may well be familial and a glance at the parents may confirm this. Nasal septal deviation is quite common, and the nose usually straightens over the first few days. Occasionally there is a frank dislocation of the nasal septum which requires relocation (see below).

There is a difference between facial palsy and asymmetric crying facies. The latter is often due to congenital absence of the depressor anguli oris muscle (DAOM); these babies can wrinkle their foreheads and close their eyes, in contrast to babies with a facial nerve palsy. The incidence of absent DAOM is about 0.6–0.8% of the population, and there is an association with congenital heart disease ([Lin et al. 1997](#)). When the diagnosis is that of facial palsy, spontaneous recovery occurs within 4 weeks in 90% of cases ([Smith et al. 1981](#)).

Ears

Look at the general shape, size and position of the ears and feel the cartilage. Low-set ears are those in which the top of the pinna falls below a line drawn from the outer canthus of the eye at right angles to the facial profile ([Fig. 14.1](#)). Abnormally small or large floppy ears are characteristic of several syndromes, and the combination

Fig. 14.1 Normal ears.

of ear anomalies and a coloboma can be a clue to CHARGE syndrome (Ch. 31). Overfolding of the helix can result from fetal constraint, and in mild cases resolves without treatment over the first weeks of life. Taping and splinting have now been shown to be remarkably successful even in cases which would previously have required surgery (Brown et al. 1986; Ruder and Graham 1996). Note any preauricular pits, skin tags or accessory auricles. Otoscopic examination does not form part of the routine examination.

The prevalence of isolated ear tags is 1.7 per 1000 with bilateral tags in 6% (Adam and Hudgins 2003). Ear pits and tags can be autosomal dominant, but it is important to assess hearing in these babies. Routine renal ultrasonography is probably unnecessary if ear pits or tags are isolated (Kugelman et al. 2002).

Hearing screening

Congenital hearing impairment in one or both ears affects about 1–2:1000 babies, and early aiding is associated with better language, communication, mental health and employment prospects. Much congenital deafness is now known to be genetic, with recessive mutations at the connexin locus accounting for many cases (Nance 2003). Universal hearing screening in the neonatal period is now in place in the UK.

Nose

Inspect the nose for its general shape and width of the bridge. If it appears abnormally wide, measure the distance between the inner canthi; this should not exceed about 2.5 cm in the term infant. The nose can appear quite squashed as a result of intrauterine compression. Occasionally the septal cartilage is dislocated and this can be recognised by deviation of the columella. Compression of the tip of the nose causes collapse and increased deviation of the nostrils in this condition, which requires treatment by an ear, nose and throat surgeon. Flaring of the alae nasi is not normal and its presence indicates respiratory illness. Babies are obligate nose breathers and hence complete nasal obstruction (diagnosed by failure to mist a mirror) causes intense respiratory distress which requires immediate investigation. Snuffy noses are quite common, but provided the

baby can breathe normally during feeding, serious problems are rarely present; if in doubt ensure that both nares are patent by passing a fine catheter through each nostril.

Eyes

The eyes should always be inspected for any gross abnormality, noting their size, dimensions and slant; check for any strabismus or nystagmus. A third of newborns have an intermittent exotropia but esotropia is not normal. Congenital cataract is the commonest form of preventable childhood blindness and evaluating the red reflex is an essential part of the neonatal examination (see below), although it is not feasible to perform full fundoscopy on every baby. Fundoscopy should of course be attempted if there is any question of abnormality.

Look for (and ask about) any discharge from the eyes. A slight mucoid discharge ('sticky eye') is very common in the first 2 days after birth, but later is likely to be due to failure of canalisation of the nasolacrimal duct. A membranous obstruction in this structure persists in 70% of neonates, but resolves spontaneously by 3 months of age in 70% and by a year in 96% (Young and MacEwen 1997). After a year probing may be required; earlier in life simple cleaning of crusts is the best treatment. Referral is not required, but beware photophobia or conjunctivitis, which suggests another diagnosis. Occasionally congenital obstruction of the nasolacrimal duct combines with an obstruction to retrograde flow to produce a dacryocystocele – a tense blue grey swelling just beneath the medial canthus. These often become infected (dacryocystitis). A frankly purulent discharge, particularly if accompanied by redness and swelling of the eyelids, should always be taken seriously and demands bacterial investigation and treatment. Subconjunctival haemorrhages are very common after birth (analogous to petechiae in the skin), and are harmless although the mother may need reassurance. The sclerae provide a guide to jaundice.

Iris

The iris is normally blue or grey in the newborn. Look for colobomas (keyhole-shaped pupil): if present there could also be a defect in the retina, and this should prompt a search for other congenital malformations. Babies with aniridia often have a poor visual outcome.

Cornea

Check that the cornea does not appear abnormally large, especially if the baby has prominent eyes. The corneal diameter is normally about 10 mm, and if this is greater than 13 mm (particularly if the cornea is also hazy) the baby might have congenital glaucoma (Ch. 33). The cornea should be bright and clear; corneal opacities deserve referral to an ophthalmologist as they can be due to herpetic ulceration, posterior corneal defects, endothelial dystrophies or abnormal metabolic infiltrations. Corneal haze after a forceps delivery usually resolves.

Cataracts can be occasionally seen with the naked eye using a bright light shone tangentially. The lens should always be examined through an ophthalmoscope held 15–20 cm from the eye. If the lens is clear you should be able to see a red retinal reflex. If there is any doubt an ophthalmological opinion must be sought urgently, as the baby may have a congenital cataract. The best results are obtained after early treatment, before there is any chance of stimulus deprivation amblyopia (Ch. 33). A dull red reflex can also be secondary to congenital melanoma or cytomegaloviral retinitis. Unfortunately the neonatal screen performs poorly in the detection

of cataract: 83/235 (35%) of cases diagnosed in the UK between 1995 and 1996 were detected at the newborn screen with further cases being uncovered at the 6-week check (Rahi and Dezateux 1999, 2001). Two-thirds were bilateral. The prevalence was estimated as 2.5 per 10 000 children. Babies in whom cataract is diagnosed must be investigated for the cause (Ch. 33). Congenital cataract is a target condition of the current NIPE programme, with the aim that 95% of all cases detected should be seen by an ophthalmologist within 2 weeks.

Mouth

Note if the mouth is of normal size or if there is micrognathia. Observe any asymmetry of the corners of the mouth and the nasolabial folds.

Inspection of the inside of the mouth is best done either while the baby is crying lustily or by making him open it (pressing down on the chin sometimes does the trick). It is better not to use a tongue depressor. One should ensure that the palate is intact by seeing it directly; palpation is not enough. It is embarrassing, to say the least, to have missed a cleft in the soft palate which later turns up as a feeding problem or nasal regurgitation.

Minor variations of normal which may be seen include: Epstein's pearls (white patches of microkeratosis akin to milia on the palate); natal teeth (which are rare in Caucasian populations but are usually best removed, especially if loose); short frenulum or 'tongue tie' (which very rarely needs treatment, Ch. 20); and bluish swellings (ranulae) on the floor of the mouth which are mucus retention cysts and need no treatment.

Neck

The baby has a relatively short neck, which should be inspected for general shape and symmetry, palpated for any lumps or swellings and tested for its full range of movements.

A webbed neck may suggest Turner syndrome (Ch. 31). A very short webbed neck with or without torticollis may indicate underlying abnormalities of the cervical spine (Klippel-Feil syndrome). Redundant skin posteriorly is one of the characteristics of Down syndrome (Ch. 31).

Cystic hygromas are soft fluctuant swellings, usually arising in the posterior triangle, which transilluminate readily. Sternomastoid 'tumours' are lesions in the sternomastoid muscle caused by haemorrhage or ischaemia resulting in secondary fibrosis (Ch. 37).

The clavicles should be palpated for fractures, especially if there is any suggestion of Erb's palsy, or if there was shoulder dystocia.

Chest and cardiorespiratory system

In spite of advances in antenatal scanning, most congenital heart disease is still unsuspected before birth, and babies still present with cyanosis, shock or a murmur. Congenital heart disease is one of the commonest groups of congenital abnormalities, being found in 7–8 per 1000 newborns. Unfortunately the neonatal examination performs no better in the detection of congenital heart disease or DDH than it does for cataract. Even in the best hands, the neonatal check fails to detect over half of all babies who are subsequently found to have significant heart disease (Ainsworth et al. 1999; Wren et al. 1999; Lee et al. 2001). A large retrospective study of all births in the northern region of the UK revealed 1590 babies with heart disease diagnosed by the age of a year from a cohort of 300 102 births (Wren et al. 1999). As many as 33% presented with signs before the newborn examination was carried out (five died), and of the

remaining 1061 babies the examination revealed an abnormality in just under half. Even when an abnormality was suspected, the usual arrangement for discharge with a 6-week paediatric follow-up was shown to be too late for some; a further nine babies died between discharge and 6 weeks. The main causes of death are hypoplastic left heart, interruption of the aortic arch, critical aortic stenosis and coarctation of the aorta.

Start by inspecting the chest. Breast swelling is quite normal at this age and a few drops of 'witches' milk' may be expressed from them. These changes are of no significance unless there is obvious inflammation, but the mother may need reassurance.

Many deductions about the cardiorespiratory state can also be made by simple inspection. As well as noting the infant's colour, the single best clue to overall function, observe the respiratory rate and other signs of respiratory distress such as retractions and grunting. If there is any doubt about the presence of cyanosis, check with a pulse oximeter. Pulse oximetry can improve the detection of congenital heart disease (Richmond et al. 2002; Koppel et al. 2003; Reich et al. 2003). About 5% of babies had a postductal oxygen saturation <95% at more than 2 hours of age, but only 1% of babies had a low result when it was checked twice: 10% of these had cardiac disease. The American Heart Association/American Academy of Pediatrics recently reviewed the question of pulse oximetry screening after 24 hours of age in some detail (Mahle et al. 2009). Ten studies with a population of 123 846 infants were summarised, with a false-positive rate of 0.035% when screening was done after 24 hours. A UK economic evaluation of the addition of pulse oximetry concluded that, of 121 infants in every 100 000 livebirths currently undetected by antenatal screening, 39 (32%) would be detected by clinical examination alone and 82 (68%) would be detected by pulse oximetry (Knowles et al. 2005). The additional cost per timely diagnosis was £4900 for pulse oximetry. Pulse oximetry was considered a promising alternative but further evaluation was recommended. Pulse oximetry can also detect babies with systemic illness (Ewer et al. 2011). Certain groups of babies are at high risk of congenital heart disease, including those with Down syndrome (40–50% have heart defects), and in these babies screening echocardiography should be performed. Pulse oximetry is not part of the standard newborn screening examination, but most hospitals now have a pulse oximeter available in the room where newborn examinations are carried out, and this is a sensible addition given the current evidence.

The respiratory rate is normally 40–60 breaths/min. A baby whose respiratory rate is persistently above 60 breaths/min needs very careful evaluation and continued observation, because this is unusual; 60 breaths/min is just above the 90th centile for the normal respiratory rate at term (Fleming et al. 2011). Remember that all infants, particularly preterm ones, can have pauses of 5–10 seconds interspersed with periods of regular breathing (periodic breathing; Ch. 27.4). True apnoeic attacks last longer than this and are extremely rare in the full-term neonate. Observe the respiratory pattern. When the infant is quiet, there should be no flaring of the alae nasi, no grunting and no retractions. On crying, some babies, especially if premature, may exhibit mild sternal or subcostal retraction.

The lungs can be auscultated at the same time as the heart, but by and large this is an unrewarding exercise if there are no respiratory symptoms.

Palpate the precordium for any thrills or a pronounced ventricular heave. The point of maximal impulse is usually found in the left fourth intercostal space inside the mid-clavicular line. Percussion of an asymptomatic infant's chest is a waste of time.

Check the peripheral pulses: a persistent ductus arteriosus with a significant left-to-right shunt produces a bounding quality. Always

palpate the femoral pulses; if they are absent or difficult to feel, suspect coarctation. Four-limb blood pressure may help by confirming a differential between the upper and lower limbs; however, normal newborns can have a difference of up to 20 ± 3.5 mmHg (Piazza et al. 1985). A difference of 20 mmHg or more suggests coarctation (Ch. 28).

Innocent heart murmurs

An innocent murmur is one that does not signify cardiac disease. Sixty per cent of normal newborns have a systolic murmur at the age of 2 hours (Braudo and Rowe 1961), but the incidence falls to around 1% by the time the routine neonatal examination is performed (Ainsworth et al. 1999; Farrer and Rennie 2003). Murmur is not the only sign of significant heart disease, and currently the neonatal examination detects only about a half of all babies who eventually present in the neonatal period with significant problems. Ainsworth et al. (1999) found a high incidence of problems when a murmur was present, but all those who care for the newborn must be aware that the absence of a murmur does not guarantee a normal heart, and vice versa. It is possible to make a positive diagnosis of an innocent murmur using clinical skills alone (Farrer and Rennie 2003), and the following features were emphasised in a study from Oxford (Arlettaz et al. 1998):

- grade 1–2/6 murmur at the left sternal edge
- no clicks on auscultation
- normal pulses
- otherwise normal clinical examination.

When a positive diagnosis of an innocent murmur was made in this way, no babies with cardiac disease were identified with subsequent echocardiography. About 23% of those who were offered echocardiography had significant cardiac disease (Farrer and Rennie 2003).

The usual origin of an innocent murmur is the acute angle at the pulmonary artery bifurcation; a few cases have patent ductus arteriosus or tricuspid regurgitation which resolves rapidly. McCrindle and colleagues (1996) suggested six features to help non-cardiologists identify significant murmurs:

1. pansystolic
2. grade 3/6 or more
3. best heard in the upper left sternal border
4. harsh quality
5. abnormal second heart sound
6. early or mid-systolic click.

Clinical examination was correct 98% of the time when similar criteria were applied to childhood murmurs, albeit by paediatric cardiologists (Smythe et al. 1990; McCrindle et al. 1996). Clinical evaluation without laboratory tests was equally effective in the hands of general paediatricians in Denmark (Hansen et al. 1995). Electrocardiogram (ECG) and chest X-ray have traditionally been used to assist in the classification of murmurs as innocent, but the clinical diagnosis is rarely changed by ECG (Newburger et al. 1983; Smythe et al. 1990) or chest X-ray (Newburger et al. 1983; Temmerman et al. 1991), and these tests should be abandoned for this purpose. An examination by an experienced colleague is a better aid to the identification of genuinely innocent murmurs. The widespread availability of echocardiography now means that this investigation, with the accompanying expert consultation, should be offered early to babies whose neonatal murmur cannot confidently be classified as innocent.

Mention of 'heart murmurs' produces intense anxiety, and talking about 'holes in the heart' is guaranteed to produce a flood of tears; now that it is clear that many are due to pulmonary vessel 'kinking' in a normal heart this is perhaps a less disturbing explanation. You

Table 14.2 Action to be taken when a heart murmur is heard

Is there peripheral circulatory collapse?	If so, immediate investigation is required
Is there central cyanosis?	Confirm with pulse oximeter. Urgent investigation if saturation low
Is there any evidence of heart failure (tachycardia, tachypnoea, enlarged liver)?	If so, immediate investigation is required
Can the femoral pulses be felt easily?	If not, check four-limb blood pressure
Are there any dysmorphic features?	If so, investigation should be done
Is the murmur grade 1–2/6, systolic, not harsh, heard at the left sternal edge only in a well baby with normal pulses?	The murmur is probably innocent. Check the result of pulse oximetry. If mother and baby are about to go home, inform parents about the problem and arrange follow-up at 3–4 weeks. Some units offer echocardiography to these infants
Is the murmur grade 3+ or more, running into diastole, or pansystolic, or is there a click, abnormal second heart sound or femoral pulses which are difficult to feel?	This murmur may be pathological. Even if the baby is well, ask a more senior colleague to listen. Watch the baby for signs of heart failure. Arrange echocardiography with the accompanying expert opinion as soon as possible. Carry out pulse oximetry, a chest X-ray and electrocardiogram as a baseline and to assist in differential diagnosis

can reassure the parents that 80–90% of murmurs found in the neonatal period will disappear during the first year, most of them within the first 3 months, and that if this is the case the baby will be discharged from the outpatient department. A practical guide to the action to be taken when a murmur is discovered is given in Table 14.2.

Abdomen

Inspection

Simple observation may yield quite a lot of information. Abdominal distension is easily appreciated, and because of the poorly developed abdominal musculature and scanty subcutaneous fat the intra-abdominal organs can sometimes be seen, particularly the bowel in premature infants. Look for any discharge or reddening of the skin around the umbilicus, which is a common source of infection. The state of the cord stump will depend on the age of the baby, but the cord usually separates by 2 weeks and a delay of longer than 30 days should be investigated (Ch. 39.1). Umbilical granulomas are common, developing in the stump after the cord falls off in an area where the umbilicus has not re-epithelialised completely. They are friable and bleed easily. They are caused by a proliferation of endothelial cells. The diagnosis is a clinical one, and it is important to distinguish a granuloma from a persistent urachus (which will occasionally discharge urine) or an umbilical polyp, which is a remnant of the vitelline duct. Granulomas can be treated with

topical silver nitrate; care must be taken not to burn the adjacent normal skin. Recently, application of table salt three times a day has been found to be a successful alternative (Derakhshan 1998). Polyps and urachal cysts need surgery.

Shortly after birth the three vessels are easily seen. A single umbilical artery is present in 4 per 1000 of newborns. There is an association with intrauterine growth restriction, and renal abnormalities were found in 7% of cases in one series (Bourke et al. 1993). A single umbilical artery in a baby with any other problem justifies further investigation of the renal tract. There is no need to investigate further for isolated single umbilical artery in a well term baby with no other problem (Deshpande et al. 2009). Further investigation of the renal tract will also be required for infants who were found to have abnormalities on prenatal ultrasonography (see Ch. 35.2).

Palpation

It is essential for your hands to be warm and for the infant to be quiet and relaxed; if necessary have him suck on a dummy or a clean gloved finger. Remember that a baby with a full stomach may well regurgitate milk if you press too hard, often to the distress of the mother who may have just spent a lot of time in feeding the baby!

Palpate the abdominal musculature; there is frequently a diastasis of the recti. Feel for the liver edge, which can be up to 2 cm below the right costal margin in normal infants. The kidneys are usually palpable with patience, and some observers have even gone so far as to state that failure to feel them indicates their absence. It is, however, probably much more important to detect any abnormally large renal masses. The spleen can often be 'tipped', but if more than 1 cm is palpable, investigation is needed. Feel for an enlarged bladder; if present try to express it and observe the urinary stream. Auscultation need not form part of the routine abdominal examination unless there is reason to suspect gastrointestinal abnormality (distension, bile-stained vomit, failure to pass meconium or bloody stools).

Record the time of passage of first stool and urine; 99% of term babies have passed their first stool and urine by 34 hours (Ch. 20, Fig. 20.1).

Genitalia

Male

Inspect the penis for length (normally about 3 cm); occasionally a penis looks deceptively short but palpation will usually disclose a respectable organ buried in suprapubic fat. True micropenis is rare but is an important sign of congenital hypopituitarism. Check the position of the urethral meatus, and if it is abnormally situated describe the hypospadias as glandular, coronal, midshaft or perineal; also inspect the shaft of the penis for curvature and compress it at its base to stimulate an erection which may reveal a latent chordee. Glandular hypospadias without chordee usually needs no treatment, but in more severe degrees of hypospadias the baby will need corrective surgery at some time before school age. All cases should have the benefit of specialist advice and the parents must be told not to circumcise the baby because the foreskin will be essential for the future repair.

Always ask about the urinary stream in boys. A poor stream may be present if there is meatal stenosis with hypospadias; constant dribbling of urine is nearly always abnormal and may indicate urethral valves.

Examine the scrotum for rugosity and feel for the testes. At full term both testes should be palpable even if retractile. Normally the

midpoint of the testis is at the midpoint of the scrotum. A retractile testis can be pulled into a normal position even if it does not remain there. A testis which is incompletely descended can only be brought down to the correct position under tension, or be wholly impalpable. About 4–5% of male term babies have at least one testis which is undescended at birth, and about 1% are still undescended at a year. If both testes are undescended at the neonatal examination the NIPE standard is for a review within 24 hours by a senior clinician and referral to a surgeon if the diagnosis is confirmed, with an appointment within 26 weeks. Babies with unilateral undescended testes should be reviewed in 6 weeks, with surgical referral for those with persistent failure or maldescent. The rationale for early treatment is that surgery may improve fertility and reduce the risk of testicular cancer. There is a strong association between undescended testis and inguinal hernia.

A bluish black discoloration of the scrotum suggests testicular torsion, especially now that very few baby boys acquire bruising of their genitalia during a vaginal breech delivery. Neonatal testicular torsion occurred some time before birth in almost all cases, and in this situation the testis is hard and not tender (Driver and Losty 1998). Referral to a paediatric surgeon is indicated, and these days many treat with analgesia and antibiotics in the immediate neonatal period, because the testis is usually already infarcted. However most recommend that the contralateral testis is fixed in the medium term.

Hydroceles can occur in the newborn period, but usually resolve spontaneously and do not require treatment. Examine the groins for indirect inguinal hernias; these are not uncommon, particularly in preterm infants, and can usually be reduced easily. If present, the mother should be warned about the symptoms and signs of incarceration/strangulation and an urgent surgical appointment organised so that early surgery can be arranged.

Female

Inspect the vulva. The clitoris and labia minora are relatively prominent in preterm infants, but at full term the labia majora should cover the labia minora although the clitoris may still appear relatively large. There is often a white mucoid vaginal discharge which is occasionally blood-stained; this is normal and the mother should be reassured accordingly. Small hymenal skin tags or mucoid cysts which resolve spontaneously may occur around the vaginal opening. Inguinal hernias are rare in the female and their presence should raise the question of other abnormalities in the genital tract. For further advice see Chapter 29, part 4.

At this stage in the examination, check the position of the anus and anal tone. A 'wink' can be produced by gently touching the anal margin.

Spine

With the baby prone, inspect the back for any obvious curvature and look for any midline abnormality over the spine and base of skull such as a swelling, dimple, hairy patch or naevus. Any of these may indicate an underlying abnormality of the vertebral column or spinal cord; occult spinal dysraphism is the most common spinal axis malformation by far, and early detection should prevent upper urinary tract deterioration, infection and permanent damage to the nervous system.

Simple sacrococcygeal pits are common and harmless; in a study from St George's Hospital, London, UK, no infant in a series of 75 with sacral dimple or pit alone was found to have a spinal abnormality (Gibson et al. 1995). The problem lies in defining the 'simple dimple' or 'simple pit', because any midline lesion other

Fig. 14.2 A simple dimple above the anus, with an erythematous macule in the midline over the spine at a higher level.

than those in or just above the natal cleft should be investigated. Similarly, any lesion at any level with a fatty pad, hairy patch or an area of atretic skin deserves further investigation. One helpful definition was given by [Kriss and Desai \(1998\)](#). These authors carefully evaluated 207 neonates with 216 dorsal cutaneous stigmata who were born in their hospital between 1993 and 1996 (the 207 were 4.8% of the births). All 207 (but not all babies) had ultrasound of the spine. Magnetic resonance imaging (MRI) was only performed if the ultrasound was abnormal. Of the 160 with 'simple' dimples – defined as being less than 2.5 cm from the anus and less than 5 mm wide, and with a midline placement and no other cutaneous stigmata – no baby had spinal dysraphism. Sixteen of the other babies were found to have abnormalities. Ultrasound was used to assess the position of the conus of the spinal cord (around L1–2 in the newborn, below L3 abnormal; [Hill and Gibson 1995](#)), and the mobility of the nerve roots, and the presence of an intrathecal mass. [Figure 14.2](#) shows an example of a 'simple dimple' but with an associated midline erythematous macule which is a trigger for investigation. [Kriss and Desai \(1998\)](#) did not attempt to assess the incidence of spinal lesions in the babies without cutaneous markers: 50–80% of late-presenting cases with spinal dysraphism have a cutaneous marker.

Ultrasound can be very helpful in expert hands, and MRI may be indicated ([Medina et al. 2001](#)). Both MRI and ultrasound are better than plain radiographs.

See Chapter 40, part 8 for more information on spinal cord diastematomyelia and midline abnormalities. Always examine the back in the midline if at follow-up a baby has a limp, foot abnormalities, bladder or bowel problems or scoliosis.

Upper limbs

Inspect the arms for shape, posture and symmetry and size. In normal upper limbs the fingertips reach to midhigh when the arms are abducted to the body. Examine the hand for any flexion deformities of the fingers and inspect the palms for the arrangement of creases. Although about 45% of individuals with Down syndrome have single transverse palmar creases, this finding occurs unilaterally in 4% and bilaterally in 1% of the Caucasian population and is a normal phenotypic variant in the Chinese population (16.8%). Polydactyly (hands and feet) is sometimes a familial trait, but look

Fig. 14.3 Erb's palsy.

carefully for any other dysmorphic features. All digital remnants should be removed surgically. Previously some were tied off with black silk and left to separate by dry gangrene, but this left a stump which produced an unsightly lump or a painful neuroma in many cases.

Observe spontaneous arm movements; stroking the hand or forearm is sometimes necessary to elicit active motion in the shoulder, elbow, wrist and hand. Test passive movements for muscle tone and range of motion. Owing to intrauterine restriction of space and activity the newborn may lack some elbow extension. Lack of active movement and pain on passive manoeuvres suggest a fracture or infection, whereas in brachial plexus or cervical spine injury passive motion is not restricted. A brachial plexus lesion is revealed by lack of movement in the arm; initially the arm is flaccid. After 48 hours an upper palsy can be distinguished from a complete palsy. In an upper root palsy (C5, 6, sometimes C7) the arm is internally rotated and pronated, there is no active abduction or elbow flexion (Erb's palsy, the 'waiter's tip' position; [Fig. 14.3](#)). The incidence of brachial plexus palsy remains around 1.6–2.9 per 1000, although a recent UK study reported a lower incidence of 0.4 per 1000 ([Evans-Jones et al. 2003](#); [Pondaag et al. 2004](#); [Lagerkvist et al. 2010](#)). In a complete palsy of upper and lower roots the arm is flail; there may be a ptosis and a Horner syndrome due to damage to the stellate ganglion adjacent to C8 and T1. Phrenic palsy should be considered in these cases. The hand may become clawed (Klumpke's paralysis). Whilst the prognosis of brachial plexus lesions is generally good, with most series reporting a recovery rate of 75–95%, this may be overly optimistic. Over half the babies in the UK series still had signs at 6 months, and about 0.5 per 1000 in the Swedish series still had deficits at 18 months of age. The results of surgical repair have improved markedly and babies who have no recovery in biceps function by 3 months should be referred to a specialist ([Gilbert et al. 1991](#)).

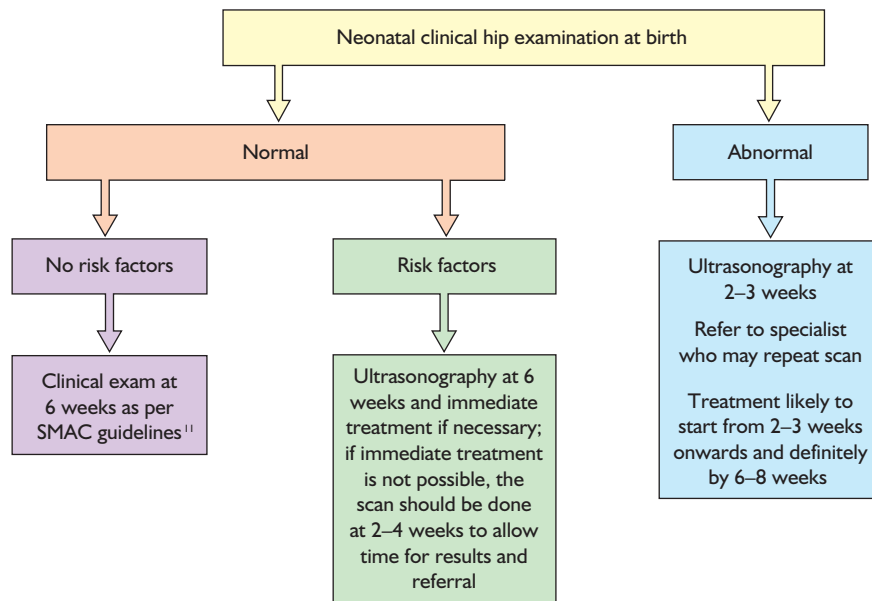

Fig. 14.4 Assessing developmental dysplasia of the hip. SMAC – Standing Medical Advisory Committee. Arch Dis Child 1986;61:921-6 (Reproduced from Sewell *et al.* (2009), with permission.)

Lower limbs

Inspect the legs and feet for posture, symmetry, general size and shape as well as for any obvious deformities. Observe spontaneous or stimulated active movements and test the range of passive movements.

The midpoint of the newborn baby's length is just above the umbilicus (compared with the symphysis pubis in the adult). Asymmetry in leg girth or length suggests one of the limb reduction defects. Some restriction of joint motion is common, secondary to limitation of intrauterine space. Babies who were vertex presentations usually have fully flexed hips and knees, but in those who were extended breech presentations the knees may remain fully extended for a few days so that the feet are somewhere near the mouth. The knees may lack up to 30° of full extension in the neonate. The tibiae are often laterally bowed and internally rotated. The feet should be inspected for their general configuration. They may provide confirmatory evidence of dysmorphic syndromes such as the 'rocker bottom' shape and short hallux in Edward syndrome. A convex 'rocker bottom' sole and a rigid foot may also indicate congenital vertical talus which will require surgery (Staheli 1993). Puffy feet and hypoplastic nails are characteristic of Turner syndrome.

The feet and ankles may be found in many positions, most of which are related to intrauterine moulding (especially if there has been oligohydramnios); much more rarely, there is an underlying neurological deficit. A calcaneovalgus position of the foot is almost invariably due to fetal position in utero and will correct in time with or without simple manipulation. If there is an equinovarus position, without using undue force an attempt should be made to overcorrect it by abduction and dorsiflexion of the foot and ankle so that the little toe touches the outside of the leg. If this manoeuvre is successful, no treatment is indicated, but deformities that cannot be so corrected (true talipes equinovarus) require urgent orthopaedic attention (Ch. 37). Simple metatarsus adductus (inturning of the forefoot) is common, and 90% resolve with no treatment.

Overriding toes are common; syndactyly is often familial; neither usually needs treatment. It is most important to explain the nature and natural history of these minor deformities to the parents.

Hips

Screening for congenital dislocation of the hip was introduced into the UK in 1966, and remains one of the most important items in the newborn examination; it is currently a NIPE target condition. This condition is now termed developmental dysplasia of the hip or DDH (Ch. 37) (Sewell *et al.* 2009). The incidence of DDH is around 1–3% of newborns. Expert management of DDH diagnosed in the neonatal period can be expected to produce a normal hip, while treatment initiated after the first year of life is usually followed by a worse result even after surgical treatment. Around a quarter of adult hip replacements in people aged 60 or less are associated with DDH (Furness *et al.* 2001). Sadly, despite initial confidence in the ability of the Ortolani and Barlow tests to detect DDH, the number of cases diagnosed late (0.2 per 1000) has not reduced and may even have increased (Sanfridson *et al.* 1991). The number of babies who require surgery for DDH has not much changed since the 1960s, at 0.78 per 1000 births (Godward and Dezeteux 1998).

The UK National Screening Committee recommends that an ultrasound be performed in babies with an abnormal clinical examination, those with a first-degree family history of hip problems in childhood, and those who were presenting by the breech after 36 weeks. Other risk factors such as talipes, oligohydramnios and torticollis are not considered strong enough evidence to mandate ultrasound. The target for performing the ultrasound examination is 2–3 weeks (Fig. 14.4).

The cornerstone of the screening strategy for DDH remains a careful history and clinical examination. The Ortolani-Barlow manoeuvres must be performed in every newborn. Details follow, although these tests are hard to describe in words and are much better taught by demonstration. A teaching aid, the 'baby hippy', is also available.

Procedure

The infant should be lying supine on a flat firm surface, with the legs relaxed, pacified if necessary by sucking on a dummy or finger. The examination may well make the baby cry and interpretation is difficult if the thigh muscles are actively contracting.

Fig. 14.5 Barlow and Ortolani test (see text for description). (Reproduced from Sewell et al. (2009), with permission.)

First, straighten out the legs and look for any obvious inequality in length, and asymmetric skin folds, although these are common and not a sensitive indicator of hip pathology. Fully flex the knees and flex the hips to a right angle. Look for any difference in the relative height of the knees, which can indicate a problem with one hip. Limited hip adduction ($<60^\circ$) in 90° of hip flexion may be the most sensitive sign for detecting a dislocated hip in neonates. Neither the Ortolani nor Barlow test will detect a dislocated, irreducible hip or a stable hip with abnormal anatomy. In normal babies it is possible to abduct the hips fully so that the knees almost touch the couch. Inability to do so may indicate a dislocated hip that cannot be reduced and is an indication for an ultrasound scan.

Carry out Ortolani's test (Ortolani 1937). This manoeuvre is designed to return a dislocated femoral head to the acetabulum. Place the middle finger of each hand over the greater trochanters, thumbs over the internal aspect of the thighs, palms over the knees. Then, simultaneously, pull the leg away from the pelvis and slowly abduct and externally rotate the hips, pressing forwards and medially with the middle fingers (Fig. 14.5). A previously dislocated hip is indicated by a definite 'clunk' as the displaced femoral head slips forward into the acetabulum, rather like engaging the gear lever of a car. This is a quite different sensation from a ligamentous 'click' which is more common (Jones 1989). It does, however, take some experience to tell the difference, the clue being whether there is any sensation of movement.

The next stage of the examination is to do Barlow's test (Barlow 1962). This test is designed to 'dislocate' an unstable hip which is in joint. Some hips are 'loose' but cannot be completely dislocated using this clinical test. Hold the hips and knees as before. With the hips at about 70° abduction, test each hip in turn by pressing forwards and medially (i.e. towards the symphysis pubis) with the finger. Normally no movement is felt, but if the hip is dislocated the femur is felt to move, again with a 'clunk' as it slips into the acetabulum. The reverse procedure is then performed by pressing backwards and laterally with the thumb. Normally there is again no

movement but a dislocatable hip will 'clunk' out of the acetabulum and will return there when the pressure is released.

Following the examination and ultrasound screening for high-risk groups it should be possible to classify the hip(s) into one of the following categories:

- normal
- a stable hip with acetabular dysplasia on ultrasound (found because of positive family history)
- a clinically unstable ('loose') hip with acetabular dysplasia on ultrasound
- a dislocatable hip (one that can be pushed out of the acetabulum and back again): Barlow-positive
- a reducible dislocated hip: Ortolani-positive
- an irreducible dislocated hip (this can be missed unless attention is paid to limited abduction; see above)
- a dislocatable or dislocated hip secondary to another problem, e.g. central nervous system disease.

For further information on the management of these types of DDH see Chapter 37.

Neurological

Although much has been written about the neurological assessment of the neonate, formal testing is seldom needed during routine examination of the newborn. More detail is contained in Chapter 40 part 1. Enough screening information can usually be gleaned from talking to the mother and from carefully watching, handling and listening to the baby throughout the examination.

The following general observations can act as a screening test, although one must take into account both gestational age (considered in more detail elsewhere) and postnatal age. The infant may be neurologically very labile during the first few days, and the most meaningful results are only obtained after this time. For a more comprehensive neurological assessment of both preterm and full-term neonates, see Dubowitz et al. (1999).

Behavioural state

Healthy term infants should move between behavioural states, spending most time in quiet and active sleep.

Posture

The undisturbed normal neonate lies predominantly in a flexed position with no lateral preference. When prone the knees are often tucked under the abdomen. The fists are clenched and the thumbs are intermittently furled. With the head in the midline the limbs are roughly symmetrical. Remember, however, that the presentation at birth can influence posture for several days.

Spontaneous motor activity

Normal infants move their limbs in an alternating fashion. Many babies may appear jittery. The prevalence of jittering was 44% in a sample of almost 1000 infants in Boston examined between 8 and 72 hours of age (Parker et al. 1990). Half were jittery solely when crying and the remainder were jittery during several behavioural states. How to distinguish jittering from fits is discussed in [Chapter 40 part 2](#).

Muscle tone and strength

This is tested by:

1. Assessing resistance to passive movements.
2. Pull-to-sit manoeuvre. Pull the baby up from the supine position by his wrists. In term infants there should be some elbow flexion and the head should come up almost in line with the body. When held sitting the head should remain erect for 2–3 seconds. The palmar grasp reflex may be tested at the same time.
3. Ventral suspension. Hold the baby in the air with a hand under the chest – he should be able to hold his head in line with his body for a few seconds and he should be able to flex his limbs against gravity.

Other general observations

Crying will almost certainly be noted at some time during the examination. Pay particular attention if it is either high-pitched or very weak, or if the infant is reported to cry excessively.

Feeding and sucking patterns will be obvious from the history.

The eyes have already been discussed; they should lie in the midposition in the orbit and move in a conjugate fashion. Note any constant deviation, persistent strabismus and nystagmus.

Suspicious neurological signs

With practice and experience one is soon able to judge from the history and handling an infant during the examination whether he is behaving normally. The purpose of such a screening procedure is to pick out those infants who merit more detailed study and follow-up. The features which should arouse suspicion and which need careful follow-up are:

- persistent failure to suck properly
- a high-pitched cry
- extreme irritability or 'starey-eyed' appearance
- abnormal posturing, e.g. opisthotonus, excessive fisting, constantly fisted thumbs
- generalised persistent hypertonia
- 'frog' posture or generalised hypotonia
- paucity of spontaneous movements, including facial expressions

- asymmetrical movements
- a history of convulsions
- midline lesions over the spine.

Biochemical screening

The list of conditions which can be identified by screening a blood sample in the newborn period grows longer every year ([Ch. 34.3](#)), and various pressure groups have campaigned for the introduction of tests for maple syrup urine disease, congenital adrenal hyperplasia, galactosaemia, biotinidase deficiency and familial hyperlipidaemia, for example. Screening for cystic fibrosis and medium-chain acyl dehydrogenase deficiency has been introduced since the last edition of this book.

Health education

The normal newborn examination represents an opportunity to provide advice about well-baby care. Information is contained in the parent-held child health records, but a selection of leaflets on the following topics should be available, and the examining doctor needs to be prepared to give advice on a range of topics, including those following. Women who reported receiving healthcare advice were more satisfied with the consultation about their newborn than those who were not offered such advice ([Wolke et al. 2002](#)). Mothers appreciated advice on topics such as jaundice, skin care, sleeping, and stool and nappy care.

Jaundice

Kernicterus is a preventable disease, and its resurgence has been a distressing feature of the otherwise welcome early-discharge policy. Jaundice is the most common reason for readmission to the maternity unit. Leaflets are available informing parents of the importance of recognising jaundice. Health professionals should follow the NICE guideline (see [Ch. 29.1](#)); babies at increased risk of jaundice should be assessed within 48 hours.

Cot death prevention (www.sids.org.uk)

Babies should sleep alone, on their backs, parents should not smoke, infant bedrooms should be kept at a comfortable temperature of about 18°C and babies should be kept warm but not over-clothed. There should be local initiatives in place for Care of the Next Infant – next siblings of infants who died of cot death.

Prevention of haemorrhagic disease of the newborn

If the parents choose oral vitamin K and the baby is to be breastfed, further oral doses of vitamin K are needed ([Ch. 30](#)). Local policies may vary as to which babies are not considered suitable for oral vitamin K prophylaxis, i.e. require intramuscular treatment because they are at high risk of vitamin K-deficiency bleeding. Examples include preterm babies, babies whose mothers are taking antituberculous or anticonvulsant drugs, and babies with evidence of liver disease.

Breastfeeding promotion

The hospital should be a 'baby-friendly' environment. The simple rules which have been shown to help promote breastfeeding ([Ch. 20](#), [Ch. 16.2](#)) should be followed. A breastfeeding counsellor should be available to provide advice and suitable literature.

Sleeping

Advice on sleeping position, co-sleeping and bedding ties in with cot death prevention. Parents may welcome suggestions on websites or books with information about sleep routines, crying babies and colic.

Safe transport in cars

The newborn period is a good time to give advice on the purchase of safe types of car seat and to encourage their use.

Maternal depression

Those working in a maternity hospital should be aware of the maternal depression scales and how to administer them. Literature informing mothers about this common and important problem and where to get help could help prevent tragedy. Screening for depression is not advocated at present.

Gestational age

The most reliable basis for assigning gestational age is an early obstetric ultrasound, and when this agrees with the mother's menstrual dates this gives the best assessment. An evaluation of the neonatal methods of estimating gestational age revealed that even the best were only half as accurate as those based on obstetric ultrasound at 15–19 weeks of gestation (Wariyar et al. 1997). The clinical methods had 95% confidence intervals of 17 days, whereas the obstetric ultrasound had 95% confidence intervals of less than 7 days. Any maturity estimation based on ultrasound obtained only during the second half of pregnancy is unreliable, and information from uterine size and date of quickening is valueless from the neonatal point of view.

The criteria used for estimating gestational age after birth may be divided into those that are based on physical maturation and those that are dependent on development of the nervous system. Many

complex scoring systems have been devised. Some criteria are more valuable than others, and little is lost by using only a few items (Parkin et al. 1976; Klimek et al. 2000). The physical items proved more robust than the items assessing tone and posture in the evaluation of Wariyar et al. and a retrospective assessment based on when the infant acquired the ability to suck and swallow reliably (34–35 weeks) was surprisingly accurate providing the infant was not oxygen-dependent (Wariyar et al. 1997). Direct ophthalmoscopy can be used to visualise the lens, although the cornea is usually too opaque for this to be possible in very preterm babies (whose eyelids may also be fused). After about 27 weeks a grading system can be applied to the vessels of the lens, which cover the entire anterior surface between 27 and 28 weeks, and reach only to the middle of the lens by 31–32 weeks and are at the periphery by 33–34 weeks (Hittner et al. 1977). This method of assessment is not much used because it requires dilatation of the pupil and is only applicable at less than 48 hours of age.

Physical characteristics

Various attempts have been made to quantify some of these changes by using scoring systems. Farr et al. (1966) used a system of 34 points derived from 11 criteria; Dubowitz et al. (1970) and Dubowitz et al. (1999) used the same physical criteria with a total of 35 points. Parkin et al. (1976) produced a much simpler scheme with 13 points derived from only four of the above criteria. This simple system proved as accurate as the Dubowitz or expanded Ballard (Ballard et al. 1979, 1991) score if half-scores were allotted (Wariyar et al. 1997). The newer Ballard score (Ballard et al. 1991) is valid for very preterm infants, although the accuracy in this group has been questioned. The appearance times of four reflexes as described by Robinson (1966) are probably most useful for premature infants <34 weeks.

For details of these scoring systems, see previous editions of this book. They are little used now that most women have early ultrasound, but remain of occasional value in a baby born after a concealed pregnancy.

Introduction

The ability of the newborn to maintain a normal temperature is critical to his or her survival yet, even in today's neonatal intensive care units, thermal care is often given a low priority (Costeloe et al. 2000; Confidential Enquiry into Maternal and Child Health 2003). Silverman et al. (1958) demonstrated a link between poor temperature control and increased neonatal mortality and morbidity over 50 years ago. The 1995 EPICure cohort demonstrated that a low admission temperature was an independent risk factor for increased mortality in newborn infants delivered at less than 26 weeks' gestation (Costeloe et al. 2000). In this cohort mortality for newborn infants who were admitted to the neonatal intensive care unit at 23, 24 and 25 weeks' gestation was 58%, 43% and 30% respectively if the admission temperature was less than 35°C. In addition the Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) Project 27/28 report of care for newborn infants at 27 and 28 weeks' gestation showed that mortality was 73% in babies with an admission temperature below 36°C compared with 59% in warmer babies (Confidential Enquiry into Maternal and Child Health 2003).

The newborn baby has many thermal homeostatic mechanisms, but a large surface area to body weight ratio and being born wet into a draughty, cold environment contribute to significant cold stress.

Body temperature control mechanisms

The production of heat energy is central to the homeostatic repertoire of the newborn (Morrison et al. 2008). Heat is generated in most tissues from the inefficiency of mitochondrial adenosine triphosphate production and utilisation. This can occur from an increase in heart rate, shivering in skeletal muscle and nonshivering thermogenesis. The increase in heart rate response is mediated by the sympathetic nervous system. When a skeletal muscle shivers or the heart rate increases then heat is generated. However shivering is not an important feature of the newborn's cold response. Instead, nonshivering thermogenesis in brown adipose tissue (BAT) plays a critical role in temperature homeostasis in the newborn infant.

Central nervous thermoreceptive mechanisms

Environmental temperature has a direct and more rapid effect on skin temperature than on core body temperature (Morrison et al. 2008). Thermal afferents from the skin to the preoptic hypothalamus promote rapid cold defence responses before core body temperature is affected. At a molecular level the transient receptor potential family of cation channels mediates sensation across a broad range of cold and warm physiological temperatures.

Central nervous system thermoregulatory pathways to and from the preoptic hypothalamus can stimulate heat production in response to a cold environment, fall in body temperature or the presence of cytokines in BAT, the heart or skeletal muscle. Cutaneous cold afferents to the preoptic hypothalamus then generate α motor neuron activity and shivering. In addition to cutaneous receptors, the preoptic hypothalamus receives afferents from core body structures such as the brain, spinal cord and abdomen via the spinothalamocortical pathway. Cold and warm receptors are included in the splanchnic and vagus nerve abdominal afferents. Deep body structures are not as susceptible to changes in environmental temperature as the skin but play an indirect role in temperature regulation.

Brown adipose tissue

BAT has a specific heat-generating function and is found in characteristic areas of the baby, such as interscapular, axillary, perirenal, and thoracic regions and between neck muscles (Blackburn and Loper 1992). In the term newborn, BAT accounts for 2–7% of the infant's weight. BAT cells begin to differentiate at 26–30 weeks' gestation, continue to develop until approximately 5 weeks after delivery and over this timeframe can increase by up to 150% (Blackburn and Loper 1992). BAT metabolism is controlled by the sympathetic nervous system, noradrenaline (norepinephrine) release and β_3 -adrenergic receptor binding to brown adipocytes (Morrison et al. 2008). Heat is generated by a facilitated proton leak across the mitochondrial membranes of brown adipocytes that uncouples oxidative phosphorylation. This occurs because of the high expression of uncoupling protein 1 (UCP1) in BAT mitochondria (Budge et al. 2003; Symonds et al. 2003). Dawkins and Scopes (1965) and Hey (1969) demonstrated that oxygen consumption almost doubled (4.8 versus 8.2 ml/kg/min) and plasma glycerol increased at an environmental temperature of 25–26°C compared with 34–35°C. These results strongly suggested that heat production occurred in BAT when the human newborn was exposed to cold. Although not specific to BAT, MRI studies have demonstrated that the preterm infant has significantly less adipose tissue and an altered deposition pattern compared with term newborn infants

(Uthaya et al. 2004, 2005). This might suggest that the preterm infant has limited ability to generate heat through nonshivering thermogenesis from both a lack of BAT and lower UCP1 expression.

Response to a cold environment

As the environmental temperature falls, the baby makes physiological and behavioural responses to maintain a constant deep body temperature. These are initiated by hypothalamic and cutaneous temperature receptors.

Physiological

Nonshivering thermogenesis results from metabolic activity in BAT (see above). Nonshivering thermogenesis is impaired in all newborns in the first 12 hours, particularly in those who are ill. Peripheral vasoconstriction also occurs in response to cold, diverting blood from the surface to the core. This is well developed in term babies but limited in very immature babies in the immediate neonatal period.

Behavioural

Whereas a child or adult will wake up and become restless when cold, the newborn infant may continue to sleep. Cold term and preterm babies tend to be more active, sleep less and adopt a flexed posture in an attempt to increase heat production and decrease heat loss.

Response to a warm environment

As the environmental temperature rises, the newborn baby attempts to prevent a rise in body temperature.

Physiological

Sweating in response to a warm environment occurs in term newborns from birth (Hey and Katz 1969; Harpin and Rutter 1982). The amount of water lost by sweating per unit area of skin is considerably lower than that lost by a heat-acclimatised adult, although the density of sweat glands is greater in the newborn. Sweating is most marked on the forehead, temple and occiput. The palms and soles only sweat in response to emotional stress. Sweating provides some measure of defence against overheating. In congenital hypohidrotic ectodermal dysplasia sweating is impaired and these babies are particularly susceptible to heat stress. Sweating is absent in babies born at less than 36 weeks' gestation but usually appears by about 2 weeks of age. Babies of opiate-abusing mothers have a well-developed ability to sweat at any gestational age. Vasodilatation in response to heat occurs in term and preterm babies, so that their skin is warm and red when overheated (Harpin et al. 1983).

Behavioural

As the environmental temperature increases, term and preterm babies become less active, sleep more and lie in an extended, sun-bathing posture (Rutter and Hull 1979a; Harpin et al. 1983).

Normal heat transfer

The normal fetus has a temperature approximately 0.5–1°C higher than that of the mother. At birth the newborn loses heat rapidly, mainly by evaporation. This can result in a drop of 2–3°C and the

triggering of the cold defence responses described above. Term newborns can increase their metabolic rate by 100% after birth but this response is blunted in a preterm or low birthweight baby (Bruck 1961). In addition the altered distribution and decreased quantity of adipose tissue and a surface area to volume ratio 3–5 times greater than that of an adult put the newborn at high risk of temperature loss.

Heat balance

The law of conservation of energy demands that, under equilibrium conditions, heat loss balances heat production. If production exceeds loss, the body temperature rises and vice versa until a new equilibrium is reached. The rate of production or loss of heat is dependent on the magnitude of the gradient between the baby and the external environment and flows from warm to cold.

Heat production

The baby produces heat by metabolic activity in all body tissues. Basal metabolic rate is difficult to measure since the newborn is rarely awake, quiet and starved, but resting levels can be measured. The resting metabolic rate (usually measured indirectly as the resting oxygen consumption) describes the metabolism of a baby who is lying still, asleep, more than an hour after the previous feed, and in thermal neutral surroundings. Under these conditions, the heat production of a healthy term newborn is similar to that of an adult when expressed per unit weight, but almost half that of an adult when expressed per unit surface area. Surface area determines a subject's heat loss and thus the relatively low heat production per unit area explains why the newborn requires a much warmer environment than an adult. Resting metabolic rate is similar in term and preterm newborn infants when expressed per unit weight, but considerably lower in preterm newborn infants when expressed per unit surface area (Fig. 15.1). Preterm babies thus require higher ambient temperatures than term newborn infants (Hey and Katz 1970).

Resting metabolic rate rises in the immediate newborn period (Hill and Rahimtulla 1965; Hey 1969). The maximum rate of heat production is approximately 50 kcal/m²/h reached by the age of 3–6 months and then remains constant into adult life. Many factors influence a newborn baby's heat production (Table 15.1), which is higher in rapid eye movement sleep than deep sleep, suggesting that the brain is metabolically highly active. The baby is also able to increase heat production in response to cold stress but there is considerable individual variation (see below).

Sources of heat loss

Conduction

Conductive heat loss involves transfer of heat from the body core to the body surface and then to objects that are in contact with it (mattress, scales). Conductive loss can be minimised by insulation, skin to skin contact and mattresses in incubators.

Convection

Heat is lost by convection from the exposed surface of the baby to the surrounding air, and is largely determined by the difference in temperature between the two. If the ambient temperature exceeds the surface temperature of the baby, heat will be gained by convection. Convective heat loss also depends on the air speed. If it is rapid, the insulating effect of still air close to the baby's surface is

Fig. 15.1 Resting metabolic rate in the newborn period when expressed per unit weight (A) and per unit surface area (B). The ranges shown are the mean values \pm 1 standard deviation. (Derived from data of Hey (1969).)

Table 15.1 Factors affecting a newborn infant's heat production

HEAT PRODUCTION IS INCREASED	HEAT PRODUCTION IS DECREASED
Awake	Deep sleep
Active	Ill (e.g. asphyxia or hypoxia)
Postfeeding	Starvation
Rapid growth	Malnutrition
Neonatal thyrotoxicosis	Hypothyroidism
Left-to-right cardiac shunt	Cyanotic congenital heart disease
Drugs (e.g. theophylline)	Drugs (e.g. chlorpromazine, caffeine)

lost (forced convection) and convective heat loss increases (wind chill factor). Convection is a major source of heat loss when newborn babies are exposed in cool, draughty rooms. Convective heat loss can be minimised by swaddling, using hats, warming oxygen and minimising draughts.

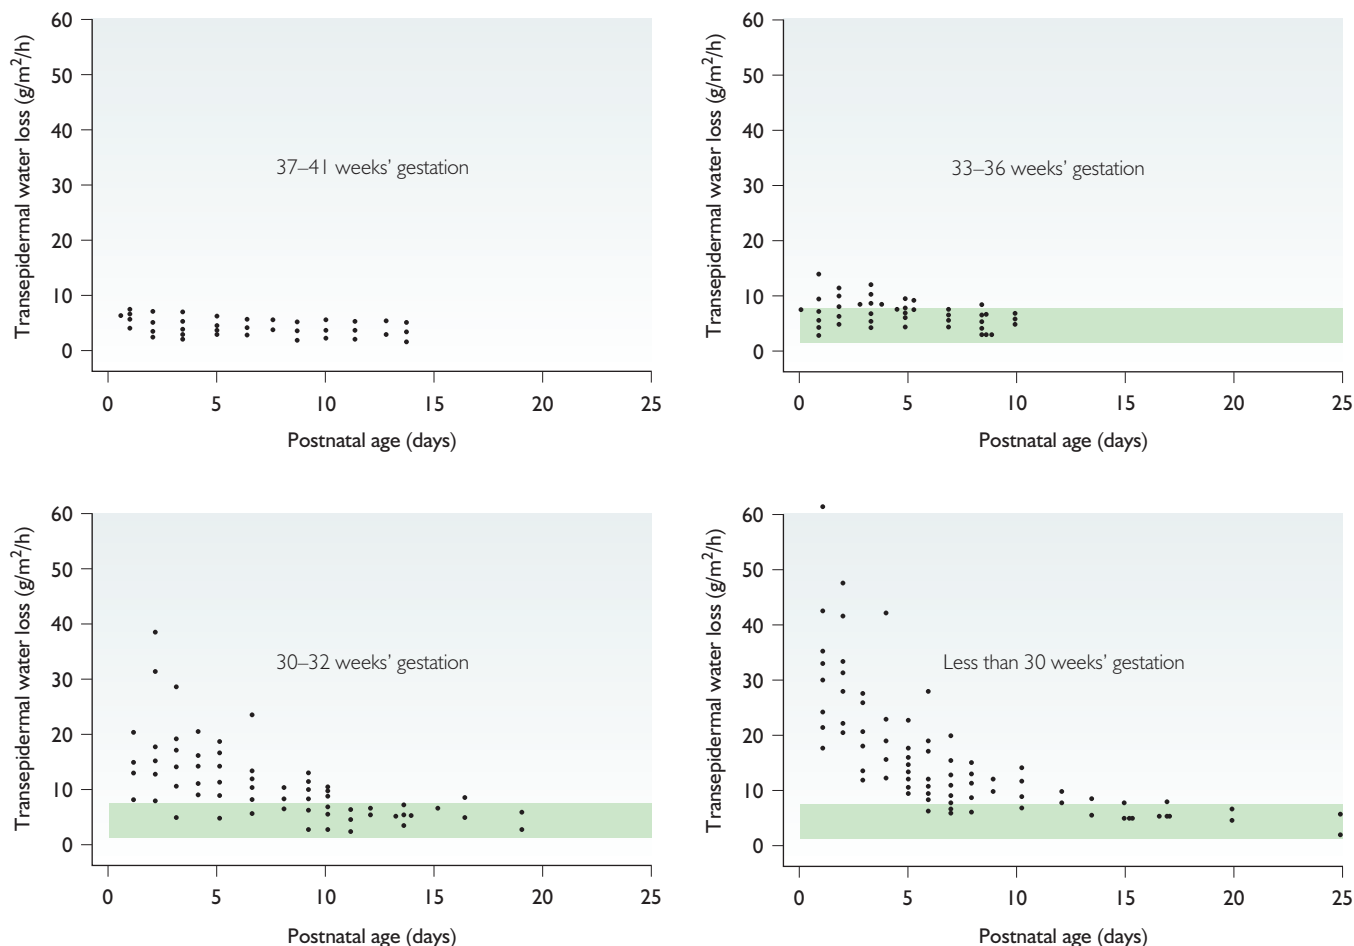

Fig. 15.2 Transepidermal water loss from the abdomen of newborn infants, showing the separate influences of gestation and postnatal age. The shaded area is the range of water loss in term infants for comparison. (From data of Harpin and Rutter (1983).)

Radiation

Heat is lost by radiation from the exposed skin of the baby to the surrounding surfaces. This loss is proportional to the difference between these surface temperatures but independent of the temperature and speed of the intervening air. Radiation loss is an important channel of heat loss when babies are naked in a delivery room or a single-walled incubator, but a source of heat gain when a baby is nursed under a radiant warmer.

Evaporation of water

As water evaporates from a baby's skin, heat is lost (each millilitre of water that evaporates removes 560 calories of heat). Under normal conditions in a term baby, evaporative heat loss amounts to about a quarter of the resting heat production (Hey and Katz 1969). About a quarter of this loss is by evaporation of water from the respiratory tract, the remainder occurring by passive diffusion of water through the epidermis (transepidermal water loss (TEWL)). Nevertheless evaporative heat loss is not a major source of heat loss in term babies, except at delivery, when the skin is wet with amniotic fluid. Mature babies have the ability to increase evaporative heat loss in response to a warm environment by sweating (Hey and Katz 1969; Harpin and Rutter 1982).

However, preterm babies have high evaporative heat losses compared with term babies (Fanaroff et al. 1972; Okken et al. 1979).

This is the result of a high TEWL, which is up to six times higher per unit surface area in a newborn baby of 26 weeks' gestation than in a term baby (Fig. 15.2) (Hammarlund and Sedin 1979; Rutter and Hull 1979b; Hammarlund et al. 1983; Jain et al. 2000). The high TEWL occurs because the immature baby's skin has a thin, poorly keratinised stratum corneum that offers little resistance to the diffusion of water. Postnatal existence rapidly hastens the development of an effective epidermal barrier (Evans and Rutter 1986), so that by about 2–3 weeks of age even the most prematurely born baby has a TEWL approaching that of a term newborn infant (Hammarlund and Sedin 1979; Rutter and Hull 1979b; Hammarlund et al. 1983; Jain et al. 2000). The high TEWL of preterm babies is further increased by trauma to the skin (Harpin and Rutter 1983). However the epidermal barrier is not influenced by use of antenatal corticosteroids (Jain et al. 2000).

Use of a radiant warmer increases evaporative heat loss by a factor of about 0.5–2.0; conventional phototherapy also increases TEWL, although it is claimed that light emitting diode phototherapy does not have this effect.

The high evaporative heat loss of babies of less than 30 weeks' gestation in the first week or so of life complicates management of their fluid balance; for advice on this topic, see Chapter 18. Reduction of this high evaporative loss can be achieved in a number of ways:

- Increasing the ambient humidity – evaporative heat loss decreases linearly as humidity rises (Chapter 18 of the 4th

edition; Fig. 18.4), so that losses at high humidity are very low (Hey and Katz 1969; Hammarlund and Sedin 1979; Thompson et al. 1984).

- Draught exclusion – for example, an incubator with low air speeds can be used (Yeh et al. 1980; Okken et al. 1982) or the baby can be nursed under a acrylic shield closed at one end (Fanaroff et al. 1972).
- Waterproofing the baby – plastic bubble blankets or clear plastic film draped over the preterm baby will reduce insensible water loss by 75% (Marks et al. 1977). Topical emollients such as soft paraffin, Aquaphor and vegetable oil have a place in waterproofing the newborn infant so that TEWL is decreased (Wananukul and Praisuwanna 2002). However a Cochrane review suggests that their routine use should be avoided because of the added risk of coagulase-negative staphylococcal infection (risk ratio (95% confidence interval (CI)) 1.31 (1.02, 1.7) and any nosocomial infection 1.20 (1.00, 1.43) (Conner et al. 2004).

Measurement of temperature

Rectal, axilla and between skin and mattress temperatures correlate well with core temperature as recorded by an electronic thermometer inserted 5 cm beyond the anus (Mayfield et al. 1984) but in general terms the peripheral temperature will underestimate the core reading. However, for most purposes the measurement of axillary temperature should be used, except during therapeutic hypothermia or when there is concern that the baby is significantly hypothermic. The normal range of rectal temperature in the newborn is 36.5–37.5°C. Although axillary temperature is generally lower than rectal temperature by about 0.5°C, the current American Academy of Pediatrics guidelines recommend adopting a similar normal range, 36.5–37.4°C (American Academy of Pediatrics, 2010). The National Institute for Health and Clinical Excellence guideline defines normal newborn axillary temperature as 'around 37°C' (NICE clinical guideline 37, Routine postnatal care of women and their babies. Issue date June 2006). More information on temperature monitoring can also be found in Chapter 19. The World Health Organization (WHO, 1997) defines mild hypothermia as 36–36.5°C, moderate hypothermia as 32–36°C and severe hypothermia as <32°C.

The goal of good thermal care is to achieve a core temperature between 36.8°C and 37.3°C with a core–peripheral difference of less than 1°C.

Rectal temperature

This can be measured using a flexible thermocouple or thermistor inserted 5 cm from the anal margin. Shallower insertion gives a falsely low recording because blood from the surface of the legs may return via venous plexuses around the anus. Rectal temperature measurement is contraindicated in necrotising enterocolitis, and carries a risk of damage to the mucosa.

Axillary temperature

Because of the risk associated with rectal temperature measurement, axillary measurement is preferred. This is the current recommendation of the American Academy of Pediatrics. In this way temperature is usually measured by an electronic thermometer with the probe placed firmly in the roof of the axilla with the baby's upper arm held against the side of the chest wall. The axillary temperature can be up to 1°C lower than rectal temperature, but the normal range is still usually defined as 36.5–37.4°C (see above).

Skin temperature

A thermocouple or thermistor lightly taped to the newborn infant's skin can be left for repeated or continuous measurements. The upper abdomen is a convenient site, as changes with environmental temperature are not as great as at a peripheral site and the skin is conveniently flat. The normal range depends on the tissue insulation, the newborn infant's size and the time after delivery. The newborn infant below 1 kg birthweight has an abdominal skin temperature close to the rectal or axilla temperature. If the temperature probe is placed between the newborn infant's back and the underlying mattress and then allowed to equilibrate, the final measured temperature is similar to core, rectal or axillary measurements (Mayfield et al. 1984).

Other estimates of core temperature

Oesophageal temperature at the level of the heart and nasopharyngeal temperature at the brim of the internal acoustic meatus are feasible and good approximations of brain or central temperature but are invasive (Seguin and Vieth 1996; Ko et al. 2001). Dollberg et al. (1994, 2000) demonstrated that an insulated transcutaneous core temperature sensor using a method that relies on the principle of zero heat flow provides a reliable estimate of rectal temperature in preterm infants. More recently a novel earphone type infrared tympanic thermometer has been used in adult surgical patients and was within a mean (\pm SD) of 0.08 (0.34)°C and 0.11 (0.55)°C of respectively oesophageal or rectal temperature (Kiya et al. 2007).

Body temperature and thermal neutrality

Thermal neutral range

This is defined as the range of environmental temperatures at which a baby's heat production and oxygen consumption (as a proxy measure of metabolic rate) are minimal and there is no sweating (Chapter 18 of the 4th edition; Fig. 18.4). In the term naked newborn the range is wider and lower than in the preterm baby. An exact definition of the thermal neutral range is complicated as some of the elaborate original work was done in an era when the addition of incubator humidity was not the norm (Bruck 1961; Agate and Silverman 1963; Scopes and Ahmed 1966). However Hey studied 123 healthy naked newborns weighing between 960 and 4760 g in an incubator with 50% relative humidity and 30–35°C temperature. The thermal neutral range at birth and 10 days of age was 34–34.5°C and 35–35.5°C, then 32.5–33.5°C and 34–34.7°C for babies with a birthweight of 2000 g or 1000 g respectively (Hey and Katz 1970). A later study based on gestation rather than birthweight determined similar ranges of the thermal neutral zone (Sauer et al. 1984). In clothed cot nursed babies an environmental temperature of 23–27°C was necessary for thermal neutrality (Hey and O'Connell 1970; Azaz et al. 1992) compared with an environmental temperature of 29°C for those with birthweight <1.5 kg (Hey and O'Connell 1970). Newborn babies are best nursed at an environmental temperature close to this range (Hey and O'Connell 1970; Hey 1971).

'Normal' temperature

The concept of a single 'normal' temperature for a newborn infant is erroneous. Clearly, a baby with a normal body temperature can be sweating or be markedly cold stressed, so body temperature is

an insensitive guide to the suitability of the thermal environment. Doctors, nurses and parents commonly assume that if a baby has a normal body temperature the ambient temperature conditions must be satisfactory. In doing so, they fail to distinguish between being cold and feeling cold. A careful observer can recognise that a baby is feeling cold before the baby actually becomes cold, by assessing the baby's posture, activity, skin colour and peripheral skin temperature. However, the very low birthweight baby is an exception. A baby of less than 1 kg has such a low heat production per surface area, limited metabolic response to cold and poor tissue insulation that he or she appears poikilothermic (body temperature drifts up and down with the ambient temperature). Measurement of body temperature in such a baby is a convenient and reliable guide to the suitability of the thermal environment.

The WHO (1997) recommendations for thermal protection in the newborn infant do not specify a gestational age, but the broad recommendations are that a newborn infant should maintain a temperature of 36.5–37.5°C to avoid cold stress with a delivery room temperature of 25°C. A 10-step 'warm chain' prevents heat loss in the newborn infant and has been successfully field-tested in eight developing countries.

Li et al. (2004) studied the range of temperature in 200 term Chinese infants over the first 72 hours after delivery. The mean (SD) rectal temperature at delivery was 36.9°C (0.28), which dropped by a mean of 0.4°C (0.34) over the first 30 minutes, then rose by a mean of 0.24°C (0.26) over 15 hours. The core temperature stabilised at a mean of 36.7°C by 48–72 hours. Skin to skin care was the only intervention necessary to restore normal temperature. In addition there is a recognised drop in core temperature of 0.5–0.6°C in the first 2 hours of nighttime sleep that develops over the first 2–4 months of age (Azaz et al. 1992; Heraghty et al. 2008).

Practical management of the thermal environment

At delivery

The ideal temperature of a delivery room or operating theatre is about 25°C, comfortable for the mother, her attendants and the baby (WHO 1997). However most delivery rooms are cooler than this, and the wet newborn infant is delivered into a draughty room. Thus, delivery itself usually presents a significant cold stress.

The newborn baby should be given to the mother to establish bonding and breastfeeding. There is evidence that skin to skin contact facilitates breastfeeding and hence this should be encouraged, although not at the cost of thermal stress; the baby should be dried and covered if the room is not warm enough. Weighing, bathing and application of name bands can all be deferred. The baby can also be clothed appropriately later. Babies who need resuscitation should be dried (if term) and placed under the radiant warmer of a resuscitaire. Preterm babies of less than 32 weeks' gestation should be placed into a polyethylene film or bag straight from delivery and without prior drying. This has been shown to be an effective way of avoiding a fall in rectal temperature in the immediate postnatal period (Vohra et al. 1999, 2004; Bjorklund et al. 2000; Cramer et al. 2005). Wrapped babies had significantly higher admission temperatures than unwrapped infants (weighted mean difference 0.63°C, 95% CI 0.38, 0.87) although there was no significant difference in mortality. The baby should remain in the polyethylene film or bag until he or she has been weighed, transferred into a humid incubator and has a temperature of >36.5°C.

In addition phase change gel mattresses and skin to skin care in combination with polyethylene film or bag are associated with a rise in admission temperature and a reduction in hypothermia of premature newborn infants on admission to neonatal intensive care (Lyon and Stenson 2004; McCall et al. 2008; Almeida et al. 2009; Singh et al. 2010).

Nursing care of the newborn infant

Parents prefer to see their baby dressed. A clothed baby who is placed in a cot covered by blankets and nursed in a warm room is usually in a neutral thermal environment and generally appears content. Clothing more than doubles the insulation, and bedding (a sheet and two blankets) further increases it, so that the resistance to heat loss of a clothed, wrapped baby is three times greater than that of a naked one (Table 15.2) (Hey et al. 1970; Hey 1983). The head is a large part of the total surface area of the baby, has a higher surface temperature and consequently loses much heat. A hat is an effective method of increasing thermal insulation, and is especially useful in low birthweight babies, who have relatively larger heads and whose trunk may need to be exposed.

The following recommendations are made for nursing healthy babies (Hey 1971):

Table 15.2 Resistance to heat loss (insulation) in an infant weighing 2.5 kg lying on a foam mattress in a cool, draught-free room. Insulation is measured in clo units (1 clo unit = 0.155°C m²/W or 0.18°C m²/kcal)

RESISTANCE DUE TO	NAKED	HAT WRAPPED IN ONE SHEET	CLOTHED IN A COT UNDER BLANKETS
1 flannelette sheet and 2 blankets around a clothed baby			0.61
1 flannelette swaddling sheet around an unclothed baby		0.81	
Thick gauze hat		0.22	0.22
Vest, napkin and long nightdress			1.25
Boundary layer of still air around the skin	0.78	0.78	0.78
Vasoconstricted body tissues	0.29	0.29	0.29
Total resistance	1.07	2.10	3.15
Reproduced from Hey (1983).			

- 2–2.5 kg: clothed, with bedding, in a room temperature of about 24°C
- 1.5–2 kg: clothed, with a hat and bedding, in a room temperature of about 26°C
- 1.5 kg: clothed, with a hat, in an incubator temperature of about 30–32°C.

Babies weighing more than about 1800 g are commonly nursed in an environment 1–2°C cooler than this. They will have a minor and clinically unimportant increase in oxygen consumption as a result.

Incubator care

A closed incubator provides a baby with a high ambient temperature whilst allowing attendants to work at a lower, more comfortable temperature. Most incubators work by forced convection: air is heated and then circulated by a fan within the canopy of the incubator at an air speed of about 20 cm/s. There are two means of controlling the heater output:

1. **Air mode.** The air temperature is set to a desired level and maintained by thermostat. The heater output is proportional to the difference between the set temperature and the actual temperature. If the incubator air temperature is just below the set temperature, the heater output will be low; if it is substantially below the set temperature, the heater will be on full power. This means that fluctuations in air temperature due to cycling of the thermostat are small.
2. **Servo mode.** The heater output is controlled by the newborn infant's skin temperature. A temperature probe is taped to the skin, preferably the upper abdomen, and the heater cycles to keep the skin temperature at that site constant. In practice, air temperature fluctuations are greater in servo mode than air mode, especially when the newborn infant is handled (Fig. 15.3).

Air mode is probably satisfactory for nursing most babies (Bell and Rios 1983). Servo mode has the disadvantages of wide fluctuations in air temperature, particularly during nursing procedures, of providing an inappropriately low ambient temperature when the baby is febrile and of lack of control when a baby with very high insensible water loss is nursed in a dry incubator (Belgaumkar and Scott 1975a; Ducker et al. 1985; Thomas and Burr 1999; Thomas 2003). The servo probe may become detached, resulting in an inappropriate air temperature. However, a Cochrane review has determined that servo control of abdominal skin temperature at 36°C reduced the neonatal death rate among low birthweight infants: relative risk 0.72 (95% CI 0.54, 0.97) (Sinclair 2002).

A naked baby nursed in an incubator loses heat predominantly by radiation, less by convection and evaporation (Fig. 15.4). Covering or clothing the baby or using a double walled incubator will reduce radiation heat losses (Marks et al. 1981). In practice, a higher air temperature setting can compensate for the radiant losses. Nursing and medical procedures disrupt the environmental temperature control, resulting in temperature instability (Mok et al. 1991; Thomas 2003).

Temperature settings used in incubators depend on whether the baby is clothed or naked, the birthweight and postnatal age. The values shown in Table 15.3 are estimates to provide an environmental temperature at the lower end of the neutral thermal range under conditions of low air speed (below 10 cm/s), moderate relative humidity (50%) and where the temperature of the inner wall is the same as the air temperature. When used in the servo mode, the required set skin temperatures are the same as those recommended for babies nursed under radiant warmers (Table 15.4).

Fig. 15.3 Fluctuations in incubator air temperature when used (A) in air mode and (B) in servo mode. In air mode, the set temperature (air) is 34°C; in servo mode, the set temperature (skin) is 36.3°C. Handling for brief spells for routine nursing procedures is indicated (↓).

Fig. 15.4 Heat production, losses and gains of 11 preterm infants (mean birthweight 1.58 kg, gestation 32 weeks, age 7 days) nursed naked in an incubator (lighter bars) and under a radiant warmer (darker bars) in presumed neutral thermal conditions. (Redrawn from Wheldon and Rutter (1982).)

Table 15.3 Average incubator air temperatures needed to provide a suitable thermal environment for naked, healthy infants

BIRTHWEIGHT (KG)	ENVIRONMENTAL TEMPERATURE			
	35°C	34°C	33°C	32°C
1.0–1.5	For 10 days	After 10 days	After 3 weeks	After 5 weeks
1.5–2.0		For 10 days	After 10 days	After 4 weeks
2.0–2.5		For 2 days	After 2 days	After 3 weeks
>2.5			For 2 days	After 2 days

Notes:

1. In a single-walled incubator, the environmental temperature needs to be increased by 1°C for every 7°C difference between room and incubator temperature.
2. Very low birthweight infants (1 kg) need higher air temperatures and a humidified incubator in the first week (Wheldon and Hull 1983; Sauer et al. 1984).
3. The values are averages but there is considerable individual variation.

Reproduced from Hey (1975).

Table 15.4 Suggested abdominal skin temperature settings for infants nursed under radiant warmers or in servo mode incubators

BIRTHWEIGHT (kg)	ABDOMINAL SKIN TEMPERATURE (°C)
<1.0	36.9
1.0–1.5	36.7
1.5–2.0	36.5
2.0–2.5	36.3
>2.5	36.0

There is a complex relationship between the water content of the air (absolute humidity), the water content of the air expressed as a percentage of the maximum possible water content (relative humidity) and air temperature (Hey 1971). Room air at 20°C in the British Isles has a relative humidity of about 50%. In a warm neonatal intensive care unit at 30°C the same room air is only about 30%

saturated, whereas in an unhumidified incubator at 37°C the relative humidity may be as low as 25%. A baby of less than 30 weeks' gestation, a day or so old, nursed in an unhumidified incubator, may have an evaporative heat loss that exceeds metabolic heat production (Fig. 15.5). The baby may therefore remain cold, even in an air temperature of 37°C. Humidification is an effective way of reducing this evaporative heat loss and maintaining a normal body temperature (Fig. 15.6). Humidity is recommended for babies below 30 weeks' gestation in the first week of life and thereafter its use depends on thermal stability (Harpin and Rutter 1985; Hammarlund et al. 1986). Modern incubator humidifiers provide good humidity control: the maximum setting is appropriate and will produce a relative humidity of 80–90% at the maximum air temperature. Humidification is probably of no advantage to the more mature baby.

Care under radiant warmers

Radiant warmers are an alternative device for nursing babies. The baby lies on an open cradle under a heat source emitting radiant energy in the frequency spectrum 700–300 000 nm. The heater is placed approximately 90 cm from the skin surface. The maximum output does not usually exceed 500 W/m (Baumgart 1984). A

Fig. 15.5 Heat production, losses and gains of an infant of 28 weeks' gestation, birthweight 1.08 kg, on the third day. When nursed naked in a dry incubator (lighter bars), air temperature 37.7°C, rectal temperature fell to 36.4°C. This is because the infant's high skin evaporative heat loss exceeded the metabolic heat production. When nursed under a radiant warmer (darker bars), set to provide a skin temperature of 36.8°C, rectal temperature rapidly rose to 36.8°C because of the high radiant heat gain. (Redrawn from Wheldon and Rutter (1982).)

Fig. 15.6 The effect of humidifying an incubator. The baby (30 weeks' gestation, 1 day old) has a rectal temperature of 35.8°C in spite of an incubator temperature of 37.3°C. When humidity is added, skin water loss falls and the rectal temperature steadily increases to 37.0°C.

Fig. 15.7 Typical recording of radiant flux density incident on the upper abdomen of an infant nursed under a radiant warmer. The infant is 32 weeks' gestation, birthweight 1.42 kg, age 9 days: the room temperature is 28.5°C. The estimated mean radiant temperature is shown on the right hand axis. Fluctuations are due to cycling of the servo control system. (Redrawn from Wheldon and Rutter (1982).)

thermistor taped to the skin on the upper abdomen is set to the desired temperature and is used to control the overhead heat output. The recommended set temperatures depend on the baby's size (see Table 15.4). Fixed output low power heaters are only suitable for brief warming procedures such as resuscitation.

The thermal environment is obviously different from that provided by an incubator (Wheldon and Rutter 1982; Baumgart 1985). The baby is exposed to cool, dry, draughty air and a markedly fluctuating radiant heat source (Fig. 15.7). Heat loss by convection is high, but heat is gained by radiation (see Fig. 15.4). Several studies have shown that newborn infants nursed under radiant warmers have higher resting levels of oxygen consumption than those nursed in incubators, although the increase is not significant (weighted mean difference 0.27 ml/kg/min (95% CI 0.26, 0.63)) (Flenady and Woodgate 2003). Evaporative heat loss is consistently higher in babies nursed under radiant warmers and is due to an increase

in water loss from the skin rather than from the respiratory tract and is significant (weighted mean difference 0.94 g/kg/day (95% CI 0.47, 1.41)) (Wheldon and Rutter 1982; Flenady and Woodgate 2003). Surface temperature distribution is also more uneven in babies nursed under radiant warmers: the peripheries are cooler than in those nursed in incubators with the same mean skin temperature. Skin and limb blood flow is increased by 50% and there is a small (5%) increase in cardiac output caused by an increase in heart rate. Radiant warmers therefore produce a fluctuating, asymmetrical thermal environment compared with the constant even temperature provided by an incubator. However, no study has shown that either method is superior to the other in terms of the mortality, morbidity and growth of babies nursed in them (Flenady and Woodgate 2003). Radiant warmers are potentially more dangerous than incubators. Overheating from probe detachment or interference can occur quickly, so the baby's surface or core temperature needs continuous independent monitoring. The increased evaporative water loss may result in hypernatraemic dehydration (Jones et al. 1976). Covering a baby who is under a radiant warmer with a rigid acrylic box will reduce insensible water losses (Yeh et al. 1979; Bell et al. 1980). However, this impairs the radiant heat exchange between the baby and warmer, producing a thermal environment with features of a warmer and an incubator. A more acceptable measure is to cover the newborn infant in a clear plastic film, resulting in lower oxygen consumption and less demand for radiant heat (Baumgart et al. 1981, 1982; Baumgart 1984).

The advantage of using a radiant warmer is that it can be an effective way of keeping a newborn infant warm (see Fig. 15.5), particularly in the first 24 hours after delivery, when considerable handling and practical procedures are necessary (Meyer et al. 2001).

The heated water filled mattress

This is an alternative method of keeping babies warm and is suitable for use in developing countries. Compared with the incubator or radiant warmer, it is cheap, simple and is not dependent on a continuous supply of electricity. The mattress is a polyvinyl bag filled with 10 litres of water and heated by a foil pad. This has a high thermal capacity and continues to provide warmth even if the power source fails. The water temperature is thermostatically controlled and regulated between 35°C and 38°C. It is safe to nurse a preterm baby in a cot on a heated water filled mattress if the baby is stable and does not have to be undressed for observation (Sarman and Tunell 1989). Temperature control, metabolic rate and weight gain compare favourably with similar babies nursed in incubators. The heated water filled mattress is therefore an excellent method for rewarming hypothermic babies, being safer than and superior to an incubator (Sarman et al. 1989). Preterm babies nursed on a water-filled mattress suffer less cold stress and may grow better than those nursed in a warm room (Greenabate et al. 1994).

Thermal environment during transport

Transporting babies from one hospital to another for intensive care is a considerable challenge (see Ch. 13 part 2). Such babies are often cold to start with, their heat losses are great and their heat production is small. Furthermore, the environmental temperature during transport may be below 0°C. Transport incubators are generally less satisfactory in terms of performance than nursing incubators. The essentials of keeping a baby warm during transport are:

- To reduce high radiant heat losses which occur if the baby has to be nursed naked – this can be achieved by covering, by use of a double walled incubator and by using a phase change gel mattress under the newborn infant.
- To reduce high evaporative heat loss – the baby should be covered in a plastic film, bubble blanket or a plastic bag.
- To observe the baby – heart rate, respiratory rate, temperature and transcutaneous oxygen tension or saturation should be measured continuously using secured portable monitoring equipment.
- To maintain a high air temperature – in babies of 1 kg or below, the required air temperature is close to 37°C. Prewarming the ambulance is recommended (see Ch. 13 part 2).
- Added humidity to assist maintenance of a normal body temperature in the immature baby, although few transport incubators currently allow this.

Surgery

The baby undergoing surgery is at particular risk of cold stress. The operating theatre air and wall temperatures are often low and the room is draughty. Starvation and sedation will blunt the response to cold stress. Furthermore, exposed organs lose water, and therefore heat, by evaporation.

Cold stress can be minimised by the following measures:

- Raise the air temperature in the theatre to 28–30°C.
- Insulate the baby before transporting to theatre: this is effectively achieved by wrapping the limbs, trunk and scalp with cotton-wool roll.
- Minimise the area of the baby exposed for surgery.
- Use a reusable forced air warming blanket (a 'bear hugger') to prevent hypothermia during major neonatal surgery (Kongsayreepong et al. 2002). A radiant heater is an alternative.

Disorders of temperature control

The baby with a low body temperature (below 36°C)

Mild degrees of hypothermia are common, particularly following delivery. More severe hypothermia (below 34°C) is less common and occurs as a result of overwhelming cold stress. In hospital, hypothermia is typically seen in small, sick preterm babies in the early neonatal period, when they are nursed in incubators and handled frequently. Use of a polyethylene bag to cover such babies in the delivery room has been shown to reduce early hypothermia (Vohra et al. 1999). The use of a radiant warmer also avoids this early hypothermia (Meyer et al. 2001).

Outside hospital, accidental hypothermia is liable to occur when a birth is unexpected or has been concealed. Hypothermia may occur in the first few weeks of life, particularly if the baby is nursed in an unheated room and the outside temperature drops below freezing. Infection (particularly pneumonia and septicaemia), serious congenital abnormality (particularly cyanotic heart disease or severe cardiac failure) and low birthweight are predisposing factors. Respiratory syncytial virus infection, especially pneumonia or bronchiolitis, is particularly associated with hypothermia in very young babies. Malnutrition also predisposes to hypothermia, by reducing tissue insulation and the metabolic response to cold. If accidental cold exposure and infection have been eliminated as the cause, hypothyroidism should be considered. Rapid screening for hypothermia is feasible using a simple chemical strip to record axillary or abdominal skin temperature (Kennedy et al. 2000).

Babies with moderate or severe hypothermia are lethargic, feed poorly and have a weak cry and reduced movements. Peripheral

oedema is common and areas of sclerema may occur in severe cases. Marked facial erythema may give a false impression but the skin always feels strikingly cold. The diagnosis will be made when rectal temperature is measured with a low reading thermometer, but will be missed if the usual clinical thermometer with a minimum reading of 35°C is used. In very severe cases (rectal temperature below 28°C), the baby may appear virtually dead, with profound cardiorespiratory depression. There are anecdotal reports of such babies being 'left for dead' but eventually making a full recovery.

There is limited information available about the safest and most effective method of rewarming hypothermic babies. However a rapid rate of rewarming has potential adverse consequences. In sheep that had hypoxic ischaemic insult who were subjected to moderate therapeutic hypothermia (30–33°C), electrical seizure activity was significantly increased when rewarming took place over less than 1 hour with no concurrent loss of neuronal cell loss (Gerrits et al. 2005). In dogs undergoing severe hypothermia (25°C) depressed myocardial contractile function with hypotension persisted through rewarming over 6 hours (Tveita et al. 1994). There are no data to suggest an adverse long term neurocognitive outcome in newborn infants during rewarming (either following hypoxic ischaemic insult or following cold exposure). However fast rewarming rates during bypass for cardiac surgery in adults have been associated with a poor neurocognitive outcome at 6 weeks (Newman et al. 1995; Grigore et al. 2002). In light of the above the current recommendation is to rewarm babies at a rate of 0.5°C per hour following therapeutic hypothermia (Azzopardi et al. 2009). In an incubator, this can be achieved using the maximum air temperature setting, or by setting the air temperature to a level which is 1–2°C higher than body temperature, and increasing it in a step-wise fashion until the baby is warm. Radiant warmers are effective in treating hypothermic babies, using a set skin temperature of 37°C. Sarman et al. (1989) found that a heated water filled mattress was superior to an incubator in rewarming 53 hypothermic preterm newborn infants. Skin to skin contact has also been shown to be a safe and effective method of rewarming (Christensson et al. 1988; WHO 1997).

Care should be taken when interpreting blood gas results in hypothermia, as pH is temperature dependent. The pH rises by 0.016 pH units for every 1°C fall in temperature, so that blood with a pH of 6.94 at 37°C will have a pH of 7.10 at 27°C. Because pH is always measured at 37°C, it is easy to overestimate and therefore overtreat a metabolic acidosis in a hypothermic newborn infant. Abdominal distension is common and necrotising enterocolitis may occur. Feeding should not start until a normal body temperature has been achieved. Haemorrhagic pulmonary oedema is a sinister sign and a common autopsy finding in babies who die from hypothermia. The reported mortality rate in severe hypothermia is 20–50%, but this includes those with congenital abnormalities or serious infection that contributed to the hypothermia. Most survivors develop normally.

The baby with a raised body temperature (above 38°C)

There are only two explanations for a raised body temperature: the baby may have an increased set point temperature or may be overheated. In a study of a large number of term babies, a raised body temperature was found in 1% in the early neonatal period (Voorla et al. 1982). Of these, 10% had a bacterial infection and 90% were overheated. Babies with a raised set point temperature behave as if they are cold. Heat production is increased, probably by nonshivering thermogenesis, and heat loss is reduced by cutaneous vasoconstriction. Pyrexia is a less reliable sign of sepsis than in older infants.

Of 371 babies aged up to 30 days, the rates of serious bacterial infection were 4.4% for those with a rectal temperature of 38.1–39.0°C, 7.6% for the range 39.1–39.9°C and 18% above 39.9°C, but only 6% had a temperature in the last range (Bonadio et al. 1990). An increased set point temperature is also seen in babies with a serious congenital abnormality of the brain, especially hydranencephaly, encephalocoele, holoprosencephaly and trisomy 13, and following severe birth asphyxia, where it is a poor prognostic sign. Such babies often have instability of thermoregulation because of hypothalamic damage (Cross et al. 1971).

Overheating is the commonest cause of a raised temperature and usually the cause of hyperpyrexia (above 41°C rectal). It is common in restless, active and overwrapped babies left in a warm room. It is also seen in babies born to a pyrexial mother. A baby's temperature at birth reflects maternal temperature and is usually about 0.5°C higher than the mother's. Epidural anaesthesia is commonly associated with an elevated maternal temperature. The baby is therefore likely to have a raised temperature and to be investigated for sepsis (Lieberman et al. 1997).

Hyperpyrexia is rare in babies and usually results from a mechanical or electrical failure of a warming device. An incubator in direct sunlight behaves like a greenhouse: short wave radiation passes directly through the acrylic canopy and long-wave radiation heats the acrylic, which in turn radiates to the baby. Serious overheating may occur if the servo probe becomes detached from the baby under a powerful radiant warmer. In early infancy, overheating occurs with excessive wrapping, during heatwaves and if babies are left in closed cars exposed to sunlight.

Hyperthermia may be associated with an increase in apnoea of prematurity (Perlstein et al. 1970; Belgaumkar and Scott 1975b). In the post hypoxic ischaemic animal model even 1–2°C hyperthermia leads to increased cerebral damage (Gunn and Bennet 2001). In addition hyperthermic piglets had worse neuropathology and behavioural scores after hypothermic cardiac arrest and newborn baboons of hyperthermic mothers had profound acidosis and hypoxia (Gunn and Bennet 2001). In light of the risks of hyperthermia the International Liaison Committee on Resuscitation (2006) newborn guidelines advocate avoidance of iatrogenic hyperthermia.

Shock, protracted fits, diarrhoea, disseminated intravascular coagulation and renal and hepatic failure occur in overheated babies (Bacon et al. 1979), but the few who have died from overheating have done so suddenly, without prior symptoms. Overheating is linked with sudden death in infancy (Guntheroth and Spiers 2001) and is described in families with a history of malignant hyperpyrexia (Denborough et al. 1982) and hypohidrotic ectodermal dysplasia (Bernstein et al. 1980).

Table 15.5 Differences between a healthy infant who is overheated and a febrile infant with a raised set-point temperature

OVERHEATED INFANT	FEBRILE INFANT
High rectal temperature	High rectal temperature
Warm hands and feet	Cold hands and feet
Core/skin difference less than 2°C	Core/skin difference greater than 3°C
Pink skin	Pale skin
Extended posture	Lethargic

The distinction between an overheated baby and one with an increased set point temperature is important (Pomerance et al. 1981; Harpin et al. 1983). The overheated baby needs a cooler environment, not a series of painful investigations to find an infective cause for the 'fever'. There are several important differences (Table 15.5). An evaluation of risk factors for sepsis is important. A useful physical sign is the degree of difference in skin temperature between the abdomen and the hand: the abdomen is always warmer than the hand; in the overheated baby the difference is less than 2°C (often less than 1°C), but in the infected baby it usually exceeds 3.5°C. The same applies to the difference between the rectal temperature and the temperature of the sole of the foot (Messaritakis et al. 1990).

Therapeutic hypothermia (see Ch. 40.4 for further details)

Hypothermia is successfully used in conjunction with cardiopulmonary bypass in babies undergoing open heart surgery, to extend the time available for surgery. Moderate whole body hypothermia (rectal 33–34°C) and local cooling of the head using a water cooled cap are well tolerated and associated with a consistent reduction in death and neurological impairment at 18 months in babies who have been subjected to asphyxial insults during labour, and are becoming widely used treatment (see Ch. 40.4) (Thoresen and Whitelaw 2000; Edwards et al. 2010).

Part 1: New perspectives in neonatal nutrition

Mary Fewtrell Sirinuch Chomtho

Since the first edition of this textbook there have been major conceptual changes in neonatal nutrition. Previously, the main objective in feeding infants was meeting nutritional needs, preventing nutritional deficiencies and promoting growth. However, increasing evidence shows that early nutrition has biological effects on the individual with important implications for later health. Thus, the way infants are fed may influence clinical course and prognosis. For instance, in preterm infants, early nutrition may influence propensity to life-threatening diseases such as necrotising enterocolitis (NEC) (Lucas and Cole 1990) and systemic sepsis, and, in the long term, have a major impact on cognitive function (Lucas et al. 1992, 1998) and disease risk in later life – notably cardiovascular disease (Singhal et al. 2001, 2004).

Until recently, early nutritional practice was underpinned largely by observational or physiological studies, or by small clinical trials designed to test for the effects of specific products on nutritional status, growth and tolerance. Our new understanding of the importance of early nutrition has emerged with the application of the pharmaceutical trial model to nutritional interventions. Randomised trials have now produced an evidence base for many areas of nutritional practice, based on short-term and, importantly, long-term efficacy and safety testing.

Nutritional programming

The concept that there are sensitive periods in early life when insults or stimuli may have long-term or lifetime effects is known as 'programming' (Lucas 1991), and has been recognised for over a century. The evidence that nutrition could operate as a programming agent was first shown in animals in the early 1960s (McCance 1962). Animal studies have shown that nutrition during critical periods in early life can programme outcomes such as changes in metabolism, endocrine function, gut function, size, body fatness, blood pressure, insulin resistance, blood lipids, learning, behaviour and longevity (Lucas 1994). Over the past few years, the long-term findings from large-scale randomised intervention studies in human infants have been emerging, showing that human infants, like other species, are programmed by early diet to a major degree. Early diet can have long-term effects on blood pressure (Singhal et al. 2001), insulin resistance (Singhal et al. 2003), blood lipids (Singhal et al. 2003), tendency to obesity (Singhal et al. 2002), bone health (Fewtrell et al. 1999, 2009), atopy (Lucas et al. 1990), cognitive function (Lucas et al. 1992) and brain structure (Isaacs et al. 2008). The effect sizes are large; in the case of cardiovascular risk factors (blood pressure, blood lipids, insulin resistance), the programming effects of early nutrition are greater than non-pharmacological

interventions in adult life, such as exercise and weight loss. These new findings must now be factored into the design of modern nutritional practices and are considered further in the following sections.

Nutrition during fetal life

An understanding of fetal nutritional physiology is vital to clinical practice. From analysis of 'reference fetuses' of different gestational ages, it is possible to calculate daily fetal nutrient accretion rates (Widdowson and Dickerson 1964; Fomon et al. 1982) and to use these as a basis for studying postnatal nutrition and its disorders. For example, the intrauterine accretion of calcium and phosphorus is substantially higher than that which can be supplied by a standard formula or mature breast milk to premature infants. Several other nutrients are laid down late in gestation, so that the preterm infant has low body stores. One example is body fat. By mid-gestation, body fat content is less than 1% of body weight; at 28 weeks, 3.5%; at 34 weeks, 7.8%; and at term, 15%. During the last month of intrauterine life, the fetus lays down about 7 g of fat per day (Widdowson and Dickerson 1964). Carbohydrate stores are also laid down relatively late. Shelley (1964) estimated liver glycogen to be about 1 g/100 g of tissue at 31 weeks and 4 g/100 g at term. Widdowson and Dickerson (1964) calculated total body carbohydrate to be 9 g at 33 weeks and 34 g at term. These data have been used to calculate the ability of infants of different gestations to withstand starvation and maintain glucose homeostasis after birth.

Total body water falls progressively from over 95% of body weight in the first trimester to around 75% at term (Kennedy et al. 1999) and continues to fall throughout infancy.

Lipid-soluble vitamins are transferred across the placenta by simple or facilitated diffusion (Friis-Hansen 1982), hence fetal blood concentrations of such vitamins correlate well with those in the mother, with the exception of vitamin E, for which fetal blood levels are around 30% of maternal values (Mino and Nishino 1973). These vitamins accumulate in fetal tissues throughout pregnancy. Blood concentrations, and perhaps body stores, are reduced in preterm infants and those of poorly nourished mothers. Water-soluble vitamins are transported against concentration gradients, mostly by active transport: fetal blood levels of vitamins B₁, B₂, B₆, B₁₂, folate and vitamin C are two- to fourfold higher than those in maternal blood. Preterm babies and babies of undernourished mothers have lower blood levels of water-soluble vitamins at birth (Baker et al. 1975).

'Biological clock' of fetal development

Intermediary metabolism

Throughout fetal life there is a progressively changing picture of enzymatic differentiation (Greengard 1977). Certain enzymes of amino acid metabolism develop late, including those concerned with the synthesis of cysteine from methionine, taurine from cysteine and tyrosine from phenylalanine, with degradation of tyrosine and production of urea (Boehm et al. 1988). As a result, low-birthweight (LBW) infants might be expected to have increased dietary requirements for certain amino acids (such as cysteine and taurine; and be at risk for possibly deleterious accumulation of others (such as phenylalanine, tyrosine and methionine; Ch. 34.3).

Key enzymes in gluconeogenic pathways (e.g. phosphoenolpyruvate carboxykinase) may not develop until near or even just after term delivery (Greengard 1977). A constant transplacental glucose infusion renders gluconeogenesis relatively unimportant in utero, and the fetal liver is more concerned with the storage of glucose as glycogen; phosphorylase and glucose 6-phosphatase ensure immediate glucose release after birth and defer the need for gluconeogenesis until around 24–48 hours of age; in contrast, the preterm neonate, born with low stores of liver glycogen (Widdowson 1981) and reduced gluconeogenic ability, is at risk of hypoglycaemia (Ch. 34.1).

Gastrointestinal tract

See Chapter 29.

Adaptations to extrauterine nutrition

Adaptation to feeding after birth involves major postnatal changes in gut structure and function and in intermediary metabolism. Although the fetal intestine is structurally mature by 25 weeks' gestation and capable of digesting and absorbing milk feeds, motor activity develops more slowly, and may limit the tolerance to enteral feeds.

Postnatally, enteral feeding appears to play a key part in triggering gut development. Studies on piglets and rats show marked structural and functional changes in the gastrointestinal (GI) tract and its adnexae following feeding – changes not seen in unfed animals. These effects are not confined to the gut: for example, enteral feeding may cause increased responsiveness to glucose by pancreatic β cells. Enteral feeding is not a new experience for the newborn infant: by the end of pregnancy, the fetus is swallowing about 500 ml of amniotic fluid daily, providing up to 3 g of protein (Friis-Hansen 1982), a similar fluid intake and about 25–50% of the protein intake of the breastfed infant at term. Enteral feeding in utero contributes to fetal nutrition and may help to prepare the gut for extrauterine feeding.

The following factors are important in regulating the adaptation of the intestine to extrauterine nutrition:

- Endocrine secretion. Corticosteroids and thyroxine are critical triggers for gut development. Adrenalectomy, hypophysectomy and thyroidectomy in animals delay gut maturation, whereas administration of glucocorticoids or thyroxine prior to delivery causes elongation of microvilli, increases the activities of the brush-border enzymes sucrase, enteropeptidase and alkaline phosphatase, and induces pancreatic enzyme secretion postnatally.

- Intraluminal factors. These may be endogenous (secreted by the GI tract) or exogenous (dietary nutrients), and act either directly on the cells of the GI tract or indirectly via effects on hormone secretion. For example, in neonatal rats, enteral feeding with sucrose increases intestinal sucrase and isomaltase, whereas lactose increases gut lactase, a finding consistent with the observed tolerance of preterm infants to lactose despite the late development of lactase in infants born at term. Surges in plasma levels of gut hormones can be induced by small, nutritionally insignificant volumes of milk, leading to the concept of minimal enteral feeding, where small volumes of milk are used to promote intestinal maturation and adaptation even when the infant is too sick to tolerate full enteral nutrition. However, although intraluminal factors undoubtedly influence GI development, they do not provide the sole trigger for ontogenetic changes, as normal maturational patterns of enzymes may occur in surgically bypassed segments of gut (Tsuboi et al. 1986).
- Minimal enteral feeding (trophic feeding) has been demonstrated to produce more ordered patterns of gut motility (Berse and Nordyke 1993) and more rapid gut transit times (McClure and Newell 1999). Although some studies have suggested that minimal enteral feeding can promote intestinal maturation, enhance feeding tolerance and decrease the time taken to reach full enteral feeds, a recent systematic review and meta-analysis (Bombell and McGuire 2009) of trophic feeding in very-low-birthweight (VLBW) infants, including data on 754 infants from nine randomised controlled trials (RCTs), concluded that there was no evidence for an effect of trophic feeding on feed tolerance or growth rate in VLBW infants; nor was there a statistically significant effect on the incidence of NEC (relative risk (RR) 1.07 (95% confidence interval (CI) 0.667–1.70). The authors concluded that further large pragmatic controlled trials are required, particularly in high-risk groups such as those born growth-restricted with absent or reversed end-diastolic flow in the umbilical artery.
- Breast milk hormones and growth factors (see Chapter 16 part 2). A large number of substances present in human milk have been demonstrated to play a role in regulating the adaptive changes that accompany the transition to enteral feeding. These include bombesin, somatostatin, epidermal growth factor, insulin-like growth factors IGF-1 and IGF-2 and nucleotides. In many cases these substances undergo only limited degradation in the stomach and appear to retain bioactivity in the intestine. Although they may not be essential for survival, the higher incidence of GI disease in infants fed formula raises the possibility that these compounds may contribute to the protective effect of human milk.
- Bacteria. Studies on the GI flora of infants fed human milk or formula suggest that the indigenous microflora are an important factor in GI development and function (see later), altering the activities of various enzymes.

Biological consequences of depriving babies of enteral feeds after birth

Exclusive intravenous feeding in rats results in decreased weight of the small intestine, pancreas and oxyntic area of the stomach, associated with a significant reduction in small-intestinal DNA and a dramatic reduction in antral gastrin content; in contrast, animal

studies have shown that other organs not directly concerned with nutrition, such as spleen and testes, remain unaffected (Johnson et al. 1975) and Heird (1977) demonstrated intestinal mucosal atrophy during parenteral nutrition, with concomitant reduction in brush-border enzyme activities. These effects may be related to the very low concentrations of circulating gut hormones found in human infants deprived of enteral feeding.

Although after short periods of parenteral nutrition in neonates tolerance to enteral feeds usually increases rapidly (in the absence of structural anomaly of the gut), it remains to be established whether prolonged avoidance of enteral feeding could deprive the neonate of critical signals for gut development.

Non-nutritional consequences of enteral feeding

When a neonate is fed, dynamic alterations occur in splanchnic blood flow, with a significant increase in velocity, which is 35% greater in formula-fed term infants than in breastfed infants. Fasting velocities are also higher in formula-fed infants (Coombs et al. 1992). In preterm infants, there is a significant correlation between the increase in mean superior mesenteric artery blood flow seen after a test feed and subsequent early tolerance of enteral feeds (Fang et al. 2001). Preterm infants fed hourly have higher preprandial blood flow in the superior mesenteric artery, with no significant postprandial change, whereas those fed 3-hourly show lower preprandial blood flow and significant postprandial hyperaemia, with a longer latency and smaller amplitude after expressed breast milk than after preterm formula (Lane et al. 1998). These findings suggest that both the frequency and composition of feeds influence splanchnic blood flow in preterm infants. Changes may also occur in pulmonary function, with decreased tidal volume, minute ventilation and compliance in VLBW infants randomised to intermittent versus continuous feeds (Blondheim et al. 1993).

Individual nutrients: physiology and dietary needs of term and preterm infants

Calculation of the nutrient requirements for term infants has traditionally been based on the composition of breast milk. However, the precise dietary intake of breastfed babies is unknown, and there is ongoing uncertainty over what should be regarded as an ideal pattern of growth during infancy, with data from animals and now humans increasingly suggesting that accelerated early growth may be associated with adverse effects on later health (Singhal and Lucas 2004). Thus, appropriate dietary goals continue to be disputed. The EC Directive Compositional Criteria for Infant Formulae (European Commission 2006) are shown in Table 16.1. All infant formula manufacturers in the UK are required by law to comply with these.

LBW babies are not a homogeneous population: their requirements and tolerance of individual nutrients are influenced by gestation, postnatal age and concomitant illness. Nevertheless, there is some international consensus on the advisable intakes for each nutrient. This field was comprehensively reviewed by the Committee on Nutrition of the European Society for Paediatric Gastroenterology and Nutrition (Agostoni et al. 2010), and by a panel of international experts (Tsang et al. 2005), who considered separately the needs of infants above or below 1000 g; a summary of the recommendations by these panels for intakes of individual nutrients

is shown in Table 16.2. The scientific and clinical basis for current recommendations for the desirable nutrient intakes in preterm infants is illustrated below.

Proteins and amino acids

The protein intake per kilogram bodyweight for the human infant is greater than for adults. In mammals, the protein content of milk correlates highly with postnatal growth rate. Nine amino acids are considered essential in human nutrition: arginine, lysine, leucine, isoleucine, valine, methionine, phenylalanine, threonine and tryptophan. However, because of the late development of certain enzymes of amino acid metabolism, the newborn infant may have a temporarily increased requirement for cysteine and histidine, and perhaps for taurine (see below).

Digestion and absorption

Luminal hydrolysis results in the breakdown of most large-molecular-weight proteins into peptides and amino acids. Most peptides are then hydrolysed by peptidases on the microvillus membrane prior to transport through the membrane, but some are absorbed intact. Although pepsin secretion is lower in preterm than term infants at birth, it is unaffected by the type of diet (Hamosh 1996). The activity of brush-border peptidases is also low in preterm infants at birth, but increases rapidly.

Protein requirements for term babies

These are discussed further in Chapter 16, part 2. The EC Directive guidelines recommend that formulas containing unmodified cow's milk protein should contain 1.1–2.1 g of protein per 100 ml of reconstituted feed. As growth velocity falls during infancy, there is a progressively decreased need for protein intake per kilogram of bodyweight. In recent years, there has been increasing speculation over the role of excess infant protein intake and increased risk of later obesity (Koletzko et al. 2009); hence there have been moves to lower the protein intakes of term infants.

Estimating the protein requirements for the preterm baby

That the rapid growth in preterm babies might greatly increase the need for dietary protein has been appreciated for over 40 years. The increasing survival of extremely preterm and extremely low-birthweight (ELBW) infants, and the appreciation that these infants often acquire substantial nutrient deficits accompanied by compromised growth during early postnatal life, has led to a re-evaluation of their protein requirements. Recent recommendations take account of a number of factors and serve as a model for the investigation of requirements for other nutrients.

Relation of protein intake to growth

Previous recommendations were based largely on estimated requirements to match the growth rate of a fetus of equivalent postconceptional age. Weight gain and linear growth are the traditional measures of nutritional status. Gordon et al. (1947) demonstrated that preterm infants gained weight more rapidly on high-protein-containing formulas than on human milk, and Davidson et al. (1967) showed that weight gain was greater in preterm infants fed a formula supplying 4 g/kg/24 h rather than 2 g/kg/24 h. High intakes of protein may also result in an increase in linear growth and a greater rate of increase in head circumference (Brooke et al.

1982; Lucas et al. 1984). Weight gain approximating to that in utero can be achieved at approximately 3 g/kg/day protein intake (Ziegler 1986; Tsang et al. 2005). Intakes of protein less than 3–3.5 g/kg/day can support intrauterine rates of weight gain, but only when accompanied by very high energy intakes, which then promote a much higher body fat than would be seen in the fetus.

Newer recommendations also recognise the need for compensation of the initial protein gap and early catch-up growth. Recent studies have highlighted the cumulative deficits in protein and energy intakes seen in preterm infants, particularly the smallest and sickest infants during early postnatal life. Even beyond this 'transition' period, actual intakes rarely match those recommended due to various clinical conditions (Embleton et al. 2001).

A factorial approach

Protein requirements may be derived using a combination of values for body composition and for nitrogen retention, obtained from balance studies. The results from a number of such studies show that protein gain increases linearly with intakes between approximately 2 and 4.5 g/kg/24 h (Ziegler 1986; Tsang et al. 2005). These calculations involve making assumptions about desirable postnatal growth performance, but the results emphasise that, in order to achieve the accretion of nitrogen at the same rate as seen in utero during the second half of gestation – estimated to be approximately 1.7 g/kg/day, although this falls at the end of gestation – the preterm infant requires substantially greater intakes of protein than would be obtained by a term infant fed on breast milk. In a sick infant in whom a temporary period of reduced nutritional intake is necessary, it is important at least to prevent catabolism. Theoretically, a protein intake of 0.7 g/kg/24 h will result in a reduction of protein turnover to the point of equilibrium (that is, zero gain and zero loss), and from a pragmatic point of view this should be the minimum acceptable daily intake.

There is also increasing focus on matching the lean body mass and protein gain of the fetus rather than simply weight gain. Fetal weight gain consists predominantly of lean body mass, such that, at term, lean body mass represents about 87% of weight. In contrast, postnatal weight gain contains a much higher proportion of fat. Hence it is generally considered that lean body mass gain is preferable to weight gain in the evaluation of postnatal growth.

Assessment of protein undernutrition

A low concentration of plasma protein is a traditional index of protein malnutrition. Preterm infants fed on human milk (banked or own mother's) may develop hypoproteinaemia after the second month of postnatal life, and this is prevented by protein supplementation (Ronnholm et al. 1982). Intakes in the range 3–4.5 g/kg/day will achieve acceptable plasma albumin and transthyretin concentrations (Kashyap et al. 1988).

Assessment of protein 'overload'

Schultz et al. (1980) showed that, compared with a breastfed control group of infants receiving 2.0 g protein per kilogram per day, a formula-fed group receiving 4.4 g protein per kilogram per day demonstrated azotaemia, a lower blood glucose, hyperaminoacidaemia (especially phenylalanine) and metabolic acidosis, and regained birthweight more slowly. However, balance and stable isotope studies (Young 1981) have emphasised that the amount of energy absorbed is critical for the rate of protein synthesis. If energy intake is low, high protein intakes cannot be utilised and the infant's metabolic machinery is stressed; in contrast, diets with high available energy and large protein intakes, of at least 4 g/kg/24 h, result in increased nitrogen retention and growth, without metabolic strain. For this reason, it is conventional to express protein (and indeed other nutrient requirements) in relation to energy intake (Table 16.2) as well as in absolute terms.

Short- and long-term outcome studies

Arguably the most important issue is whether early protein intake could have longer term consequences, either adverse or beneficial. A recent systematic review (Premji et al. 2006) identified five RCTs comparing different protein intakes in preterm infants and reported improved weight gain and higher nitrogen accretion in infants receiving formulas with higher protein content (>3 but <4 g/kg/day). None of the studies examined cognitive outcome. However, a study in 495 ELBW infants (Ehrenkranz et al. 2006) suggested that in-hospital growth velocity had a significant impact on neurodevelopment and growth outcomes at 18–22 months postterm. In another study, preterm infants randomised to receive a preterm formula containing 2 g/100 ml protein showed both better short-term growth than those fed a standard term formula containing

1.45 g/100 ml and improved neurodevelopment 7.5–8 years later (Lucas et al. 1992). Finally, a recent observational study reported that higher protein and energy intake during the first week of life in ELBW infants was associated with higher Bayley mental developmental index (MDI) scores at 18 months and with a lower likelihood of restricted linear growth. Each 1 g/kg/day increase in protein during week 1 was calculated to be associated with an 8.2-point increase in Bayley MDI (Stephens et al. 2009).

Despite increasing evidence supporting the clinical benefits of an adequate protein intake, a study by Goldman et al. (1974) cautioned that excessive intakes could have adverse effects. A total of 304 infants below 2000 g were randomised to 2% or 4% protein diets, providing, respectively, 3.0–3.6 and 6.0–7.2 g protein per kilogram per day. Infants below 1300 g in the high protein intake group had a markedly higher incidence of low IQs (below 90) by Stanford–Binet score at 5 years of age. The incidence of strabismus in infants below 1700 g fed on a high protein intake was also increased.

Protein quality

All protein supplies are not equal and it is recognised that net protein utilisation (N retained/N intake) differs with different feeding regimens. Whey proteins have a lower concentration of aromatic amino acids (tyrosine and phenylalanine) than are found in caseins; the studies by Goldman et al. (1974) were performed with high-casein formulas (like cow's milk), but most modern formulas are whey-predominant, reducing the possibility of hypertyrosinaemia and hyperphenylalaninaemia. Whey is also a good source of cysteine, a potentially essential amino acid in the newborn period (see above). However, there are still considerable differences in the protein composition of modern infant formulas compared with breast milk. A large part of this difference relates to the lower concentration of α -lactalbumin and higher concentration of β -lactoglobulin in bovine milk. It is now possible to make whey fractions from bovine milk with lower β -lactoglobulin and higher α -lactalbumin. These fractions contain higher concentrations of essential amino acids, particularly tryptophan and cysteine. Their addition to infant formulas may result in plasma amino acid patterns closer to those seen in breastfed infants, and allow a reduction in the total protein levels, with potential benefits for the infant's growth pattern (Lien et al. 2004; Sandstrom et al. 2008).

Amino acid composition

There is increasing focus on amino acid requirements rather than protein requirements, on the basis that infants require specific amino acids, not proteins. Little is known about the optimal intakes of specific amino acids. However, a different amino acid composition of protein may well alter the total amount required. Breastfed infants have higher plasma and urine taurine concentrations and a higher rate of synthesis of bile acids than those fed on formula; the latter may partially explain the better fat absorption of infants fed human milk rather than formulas (Gaulle et al. 1977). Rhesus monkeys fed a taurine-deficient formula for the first 6 or 12 months of life show abnormal retinal structure, although the abnormalities show some degree of spontaneous regression by 12 months even when the animals remain on the deficient diet (Imaki et al. 1993). A randomised trial of taurine supplementation in formula-fed preterm infants (Tyson et al. 1989) showed no effect on growth, behaviour or electroretinograms, but some evidence of more rapid auditory maturation in the supplemented group at the equivalent of term (as assessed by brainstem-evoked response). More recently, Wharton et al. (2004) have shown that preterm infants with the

highest plasma taurine concentrations during the neonatal period have better numeracy skills during adolescence and better development of the related parietal cortical grey matter. Thus, it seems prudent to add taurine to LBW formulas to achieve concentrations similar to those of breast milk.

Glutamine is used as a fuel by the small intestine and as a precursor for the synthesis of purine and pyrimidine bases. Numerous studies in animals and adult humans have demonstrated that it has beneficial effects on the GI tract, including the maintenance of structure and function during parenteral nutrition. A systematic review that included data from 2365 preterm infants who participated in seven randomised trials of either enteral or parenteral glutamine supplementation concluded there was no evidence of a beneficial effect of supplementation on mortality or short-term morbidity. The single study that assessed longer term outcomes found no effect on neurodevelopment at 18 months' corrected age (Tubman et al. 2008).

Arginine is a precursor for the synthesis of nitric oxide, which in turn is important as a regulator of vascular perfusion. Plasma arginine concentrations have been found to be inversely related to the severity of respiratory distress syndrome, and low concentrations have been reported in infants who develop NEC. A single randomised trial of arginine supplementation (1.5 mmol/kg/day, given either enterally or parenterally) versus placebo in preterm infants found a significantly reduced incidence of NEC in supplemented infants (RR 0.24; 95% CI 0.10–0.61), with no adverse effects. However, given the high incidence of NEC in the study population, the data are insufficient at present to support a practice recommendation. A multicentre randomised controlled study of arginine supplementation in preterm neonates is needed, focusing on the incidence of NEC, particularly the more severe stages (2 or 3).

Fat

Digestion and absorption

Fat provides about half the energy for infants fed human milk, and its digestion commences in the stomach, catalysed by lingual lipase and gastric lipase (Hamosh 1996). Gastric lipolysis is quantitatively greater in the infant than in the adult, and the output and activity of lipases in the preterm infant are equal to those of adults maintained on a high-fat diet. Although gastric function and the production of lipase are unaffected by infant diet, the extent of fat digestion is greater in babies fed human milk (25%) than formula (14%), probably because of the structural differences between triglyceride in human milk fat globules and that in formula fat particles. Both lingual and gastric lipases are able to penetrate the milk fat globule membrane and digest triglyceride without disrupting its structure. The contribution of pancreatic lipases is relatively lower in infants than in adults. However, the bile salt-stimulated lipase (BSSL) present in human milk may contribute significantly to fat digestion. BSSL is present in high quantities even in the milk of mothers who deliver prematurely, and its concentration is independent of milk volume. Unlike gastric and pancreatic lipases, BSSL shows no positional or fatty acid specificity and is able to produce free fatty acids which are more easily absorbed than mono- or diglycerides at the low bile salt concentration seen in newborn infants.

The products of fat digestion are absorbed, resynthesised as triglycerides and secreted mainly into the lymphatic system as chylomicrons, and thence into the blood via the great veins. The foregoing applies to long-chain triglycerides, which are best absorbed if they are unsaturated. In contrast, medium-chain triglycerides

(MCTs: 8–10 carbon atoms to the chain) are handled quite differently: their digestion is largely independent of bile salts; they are well absorbed, hydrolysed or intact, and pass to the liver via the portal system. Faecal fat excretion in newborn infants is greater in infants fed on cow's milk than in those fed on human milk or vegetable fats.

Most modern formulas contain a mixture of animal and vegetable oils, adjusted to mimic the pattern of fatty acid saturation and chain lengths found in breast milk. When compared with human milk, such fat mixtures have a reduced content of fatty acids esterified to glycerol in the 2 position and an increase in those esterified in the 1 and 3 positions. The latter undergo hydrolysis in the gut, releasing palmitic acid, which is poorly absorbed and tends to form calcium soaps; this may be partly responsible for the harder stools seen in formula-fed infants, and could influence calcium absorption. A recent review identified nine publications in preterm or term infants in which 'standard' infant formulas containing high palmitate concentrations were compared with either low palmitate formulas or formulas containing a modified synthetic fat blend (Betapol) with a high proportion of fatty acids esterified in the 2 position to mimic that found in human milk (Koo *et al.* 2006). Standardised results from these studies were consistently positive in favour of the low/synthetic palmitate groups with respect to intestinal fractional absorption of fat, palmitic acid and calcium. Total body bone mass was also significantly higher in two studies (Kennedy *et al.* 1999; Koo *et al.* 2003), suggesting that increased calcium absorption results in measurable biological effects in the short term (Kennedy *et al.* 1999). However, follow-up of one of these cohorts at age 10 years found no persisting effect of the intervention on bone mass, suggesting that any effect may be transient (Fewtrell *et al.* unpublished observations).

Fat requirements

Because there are clinical and physiological ceilings on the amount of dietary energy that it is desirable to supply as carbohydrate or protein, a minimum of around 30% of dietary energy needs to be supplied as fat. Linoleic and alpha-linolenic acids are essential fatty acids for the development of the brain and for prostaglandin synthesis. Essential fatty acid deficiency is also associated with skin lesions and retarded growth.

Two other dietary factors are important for lipid metabolism. Carnitine plays a key role by facilitating transport of long-chain fatty acids across the mitochondrial membrane prior to their oxidation (Wharton 1987). Carnitine deficiency during the neonatal period has been reported in infants who experience intrapartum hypoxia and acidosis (Bayes *et al.* 2001). Preterm and small-for-gestational age (SGA) infants may have impaired endogenous carnitine synthesis, and if carnitine intake is deficient (as in total parenteral nutrition (TPN)) plasma and tissue concentrations fall. Nevertheless, there is currently insufficient evidence to judge whether such infants are put at clinical risk from a low-carnitine diet is uncertain. A randomised trial found that preterm infants who received supplemental carnitine in parenteral nutrition did not demonstrate any reduction in apnoea of prematurity, ventilatory requirements or need for supplemental oxygen therapy compared with those who received placebo (O'Donnell *et al.* 2002). Standard formulas usually contain similar concentrations of carnitine to those in breast milk, but some preterm formulas have additional carnitine.

Choline is required for phospholipid and acetylcholine synthesis (Wharton 1987). About half the choline requirement is derived from the diet. Human and cow's milk-based diets provide a sufficient intake.

Inositol, a six-carbon cyclic polyalcohol sugar, is a component of membrane phospholipids, and compounds containing inositol are important in signal transduction. Breast milk, particularly colostrum, contains high concentrations, whereas the levels in infant formulas are lower and intravenous feeding solutions have none. At present, it is recommended that all preterm infants receive supplementation based upon the level of inositol in human milk. A systematic review of three RCTs of inositol supplementation in preterm infants concluded that supplementation results in a statistically significant and clinically important reduction in the risk of chronic lung disease, retinopathy of prematurity (stage 4 or needing therapy), intraventricular haemorrhage (grade III–IV) and death (Howlett and Ohlsson 2003). The authors suggest a multicentre RCT of appropriate size is required to confirm these findings.

Essential fatty acid requirements

Two groups of long-chain polyunsaturated fatty acids (LCPUFAs, i.e. polyunsaturated fatty acids with greater than 18-carbon chain length) have received increasing interest in recent years: these are homologues of linoleic acid of the n-6 series (dihomogammalinolenic acid, arachidonic acid) and of α -linolenic acid of the n-3 series (eicosapentaenoic acid, docosahexaenoic acid (DHA)). The LCPUFAs are synthesised from the precursor essential fatty acids by a process of chain elongation and desaturation (Fig. 16.1). They are found in high concentrations in the phospholipids of cell membranes, notably in the central nervous system (O'Brien *et al.* 1964). In addition, arachidonic acid, dihomogammalinolenic acid and eicosapentaenoic acid are precursors for eicosanoids – important modulators and mediators of a variety of essential biological processes.

Rapid accumulation of LCPUFAs in the brain, particularly DHA, occurs from the third trimester to 18 months postpartum

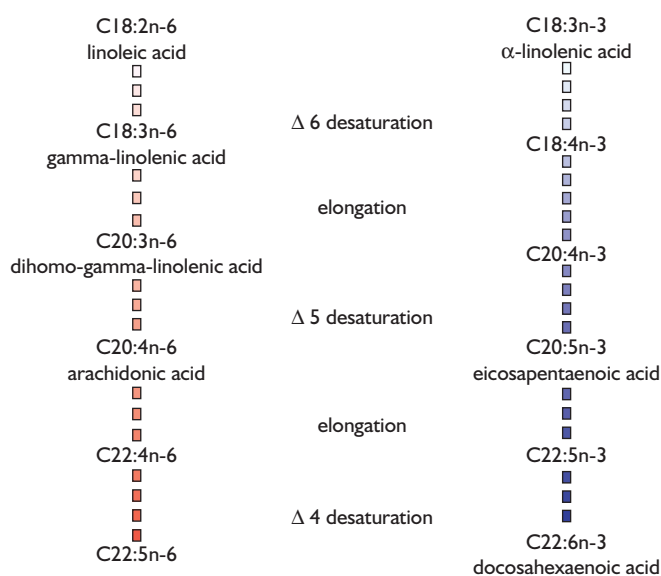

Fig. 16.1 Major steps in the formation of long-chain polyunsaturated fatty acids (LCPs) from the C:18 essential fatty acids. Unsaturated fatty acids contain at least one double bond between adjacent carbon atoms: the number of double bonds is represented by 1n, 2n, 3n, etc. LCPs are further classified by the position of the first double bond from the methyl or omega end of the hydrocarbon chain, represented as -3, -6, -9 or -3, -6, -9. Linoleic acid (C18:2n-6) thus has a chain length of 18 carbons with two double bonds, the first of which is at the sixth carbon atom from the omega end.

(Clandinin et al. 1981). Human milk contains both the precursor essential fatty acids and adequate LCPUFAs for structural lipid accretion (Clandinin et al. 1980), but infant formulas traditionally contained only the parent essential fatty acids, the assumption being that the infant could synthesise LCPUFAs from these. However, term and preterm infants fed on formulas which contain minimal LCPUFAs have been shown to have lower red cell LCPUFAs and lower LCPUFAs in the phospholipids of the cerebral cortex and subcutaneous tissues than infants fed breast milk (Carlson et al. 1986; Farquharson et al. 1992, 1995; Makrides et al. 1994). Largely on the basis of the biochemical data, ESPGHAN (1987) recommended several years ago that formulas for LBW infants should be enriched with metabolites of both linoleic and linolenic acids, approximating the levels typical of human milk; indeed, the majority of preterm and term infant formulas now contain preformed LCPUFAs. However, although there is clear evidence that supplementing infant formulas with LCPUFAs results in biochemical improvement, there is less evidence of lasting clinical benefits; recently updated systematic reviews concluded there was no evidence for a clinical benefit of LCPUFA supplementation of term (Simmer et al. 2008a) or preterm (Simmer et al. 2008b) infant formula. In the most recent and largest trial conducted in this field, preterm infants (<33 weeks' gestation) were randomised to receive either high DHA (1% of total fatty acids) versus a typical current DHA intake (0.3%) achieved by a combination of supplementing mothers who were expressing milk for their infant and the use of DHA-supplemented formulas. No effect of high-dose supplementation was seen overall at 18 (Makrides et al. 2009) or 26 months' (Smithers et al. 2010) corrected age, although girls had significantly higher Bayley MDI at 18 months. Longer term follow-up studies are currently in progress, testing for effects of LCPUFAs on health outcomes, including cardiovascular risk as well as cognitive function.

Term babies

The EC Directive guidelines (European Commission 2006) recommend that the fat content of infant formulas should lie between 2.6 and 4.1 g per 100 ml of feed. The guidelines also specify levels for alpha-linoleic acid (not less than 12 mg/100 kcal) and linoleic acid (300–1200 mg/100 kcal), with the linoleic/alpha-linoleic ratio between 5 and 15, for term infant formulas. However, there is currently no requirement to add LCPUFAs, although, if added, their content shall not exceed 1% of total fat for n-3 LCP and 2% of total fat for n-6 LCP. Furthermore, the DHA content shall not exceed that of the n-6 LCP and the eicosapentaenoic acid content shall not exceed the DHA content.

Preterm babies

The main problem with dietary fat in preterm infants is the increased tendency to steatorrhea. Reduced fat absorption in LBW infants relates to:

- reduced pancreatic lipase and carboxylic ester hydrolase activity
- reduced bile acid pool size and secretion rate: the duodenal bile acid concentration may well be below the critical level for micelle formation
- possible reduction in activity or excretion of lingual lipase.

Fat absorption from fresh breast milk is approximately 90%, but the observed range is enormous. Williamson et al. (1978) found that fat absorption from expressed breast milk fell to 55% in VLBW infants fed pasteurised milk, and to around 45% when the milk was

boiled. These data may reflect loss of the bile salt-stimulated lipase found in human milk due to heat treatment.

A controversial issue is the addition of large quantities of MCTs to specially designed preterm infant formulas, largely because such babies absorb palmitic acid (n-16) poorly. The MCT content of human milk is low (less than 2% total fatty acids), whereas modern preterm formulas may contain up to 40% of the fat in this form. MCTs may spare dietary nitrogen and enhance calcium and magnesium absorption (Tantibhedyangkul and Hashim 1978). However, a review that included eight small randomised trials of MCT versus long-chain triglycerides in preterm infants concluded there was no evidence for an effect of MCT on short-term growth, GI intolerance, or NEC, although larger studies would be required to confirm these findings and to examine longer term outcomes (Klenoff-Brumberg and Genen 2003).

Carbohydrate

Physiology

The carbohydrate in human milk is almost entirely lactose, which provides 40% of ingested energy (Kien 1996). Other carbohydrates, e.g. sucrose and maltodextrins, may be hydrolysed efficiently by active brush-border sucrase, maltase and isomaltase, even in preterm infants, and starch or glucose polymers can be digested by salivary and pancreatic amylase, by amylase present in human milk, and by intestinal mucosal hydrolases.

Dietary lactose undergoes one of two processes: hydrolysis into glucose and galactose by the intestinal brush-border lactase, followed by absorption of glucose and galactose, or fermentation in the colon, with production of various gases and short-chain fatty acids. Energy from the latter can be absorbed, compensating at least in part for the inefficiency of dietary energy utilisation. Short-chain fatty acids administered into the colon have also been shown to stimulate intestinal growth following gut resection in animal models, and prevent mucosal atrophy after resection and TPN. There is controversy over the possible role of lactose fermentation in the development of NEC. However, although there are some experimental data linking excessive carbohydrate fermentation in the small intestine with an inflammatory condition resembling NEC, there is little evidence that colonic lactose fermentation is a primary factor.

Galactose and glucose are absorbed by the same carrier mechanism, and more than 90% reaches the portal vein. Most galactose is removed by the liver on first pass, and appears to be preferentially used for glycogen synthesis rather than conversion to glucose.

There is currently intense interest in the prebiotic role of oligosaccharides in human milk. Prebiotics are defined as non-digestible food ingredients that selectively stimulate the growth and/or activity of one or more bacteria in the colon, and therefore benefit the host. They promote the bifidogenic-dominant colonic microflora observed in breastfed infants, which in turn protects the infant from enteropathogenic bacteria. Human milk contains hundreds, if not thousands, of oligosaccharides; the composition is genetically determined with wide interindividual variation, making it difficult to define (and therefore to mimic) the oligosaccharide content of breast milk. Cow's milk formulas traditionally contained no oligosaccharides, but, in recent years, oligosaccharide mixtures such as GosFos (a mixture of 90% galacto-oligosaccharides with 10% fructo-oligosaccharides) have been added. Randomised trials of supplementation of formula with oligosaccharides have shown enhanced colonisation with beneficial intestinal flora in both term and preterm infants, but there is less evidence for effects on clinical outcome (Osborn and Sinn 2007).

Term infants' requirements

The EC Directive recommendation (European Commission 2006) for carbohydrate intake is that it should be between 5.5 and 10.0 g per 100 ml of reconstituted feed, and that the lactose content should be above 2.7 g/100 ml (Table 16.1). Other carbohydrate sources that are permitted in modern formulas are maltose, sucrose, glucose, maltodextrin, glucose syrup and precooked or gelatinised starch.

Preterm infants' requirements

It is difficult to infer from physiological studies which carbohydrate is optimal for LBW infants. Lactose may enhance gut absorption of calcium and magnesium and may encourage a favourable gut flora; excessive intakes may result in diarrhoea and metabolic acidosis, yet in practice a high lactose intake in preterm infants is usually well tolerated.

One approach in the design of preterm formulas is to use lactose as the principal carbohydrate source, but to replace a proportion of the carbohydrate with glucose polymers in order to prevent excess osmolality (see Table 16.2 for recommended intakes).

Energy

The fundamental energy (E) equation is:

$$E_{\text{intake}} + E_{\text{stored}} = E_{\text{expended}} + E_{\text{excreted}} \quad (1)$$

Energy expended may be subdivided further:

$$E_{\text{expended}} = E_{\text{BMR}} + E_{\text{activity}} + E_{\text{synthesis}} + E_{\text{thermoreg}} \quad (2)$$

where E_{stored} is the energy deposited during growth, E_{BMR} is the basal energy requirement, E_{activity} is the additional cost of muscular activity, $E_{\text{synthesis}}$ is the metabolic cost of growing (excluding energy stored in new tissue) and $E_{\text{thermoreg}}$ is the energy cost of maintaining body temperature.

Traditionally, the tools used to derive these values have been energy balances and indirect calorimetry (energy expenditure calculated from oxygen consumption and carbon dioxide production) performed under different experimental conditions during rest. More recently, the 'doubly labelled water method' has been used to measure total energy expenditure over periods of several days. This non-invasive method depends on monitoring the differential disappearance from the body of two stable (non-radioactive) isotopes, ^{18}O and deuterium, both administered orally as labelled water.

There has been dispute over which conversion factors should be used for either human or cow's milk to derive the metabolisable energy content (the gross energy of the food from bomb calorimetry minus the energy lost in the stools and urine) from macronutrient concentrations. Although not entirely appropriate to the milk-fed neonate, the conventional Atwater conversion factors derived by Southgate and Durnin (1970) are commonly used.

Term infants' requirements

The EC Directive guidelines recommend that formula should contain similar energy contents to those reported in human milk, i.e. 60–71 kcal/100 ml of reconstituted feed. However, from studies employing the doubly labelled water method, Lucas et al. (1987) suggested that infants fed on human milk may receive lower energy intakes than those commonly reported and those employed in modern formulas – they obtained a value of 58 kcal/100 ml at 3 months; this may explain why modern formula-fed term infants grow faster than their breastfed counterparts.

Term SGA infants have been reported to have energy expenditures 5–10% higher than infants who are appropriate for gestational age, and may therefore benefit from increased energy to promote catch-up growth. In one study, a high-energy formula resulted in a marginal increase in weight gain and head growth (Brooke and Kinzey 1985). However, it is likely that both extra energy and protein are required simultaneously.

Preterm infants' requirements

The energy requirements for preterm infants cannot be calculated without some consideration of the desired composition of weight gain, as the deposition of different types of tissue incurs different energy costs. For example, 9 kcal are stored in each gram of fat, compared with 4 kcal per gram of protein. Thus, a weight gain high in fat will require more energy to be stored than one high in protein. As previously mentioned, the ratio of energy to protein is important in determining the relative amount of lean tissue versus fat which is deposited. These considerations are not just theoretical, as the different diets used for preterm infants do result in variations in the composition of tissue deposited (Fig. 16.2). At present it is not known whether it is best to aim for a weight gain with 15% fat (as in the fetus) or nearer 40% fat (as in a term infant), and, unless this can be shown to have implications for future health, one might argue that it is academic. The results to date have been conflicting: DeGamarra et al. (1987) and Cooper et al. (1989) both found no differences in growth at 2 or 3 years of age in preterm infants who had shown wide differences in adiposity as infants. However, Agras et al. (1990) reported that greater adiposity at birth was a predictor of greater fatness at 6 years of age. In our own randomised trial of diet in preterm infants we found major differences in growth rates between diet groups during the neonatal period, but no differences in either growth (Fewtrell et al. 1999) or body fat mass or lean mass (Fewtrell et al. 2004) between diet groups at follow-up in childhood or early adult life (Fewtrell et al. 2009a).

All the components of the energy equation have been either measured or estimated in preterm infants, in order to calculate the optimal energy intake. The daily energy cost of activity is around 10 kcal/kg; the cost of thermogenesis, 10 kcal/kg/24 h (depending on thermal environment); and, at growth rates of 15 g/kg/24 h, the cost of tissue synthesis is about 10–20 kcal/kg (Reichman et al.

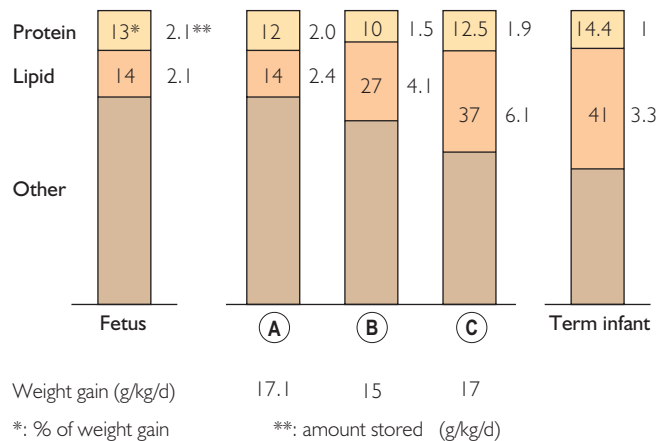

Fig. 16.2 Weight gain composition of the fetus (32–36 weeks) and of the term infant (0–4 months), compared with that of preterm infants fed different diets. (A) Protein-supplemented pooled human milk. (B) Pooled human milk. (C) Preterm formula. Figures represent the percentage of weight gain as protein or fat.

1982; Wharton 1987). The remaining component of energy expenditure, basal metabolic rate (BMR), cannot be measured in preterm infants as it requires at least a 12-hour fast. However, total energy expenditure, which includes all four of these components, has been measured over 5 days with both the doubly labelled water method and indirect calorimetry in four preterm infants (Roberts et al. 1986) growing at a mean rate of 15 g/kg/24 h, and was 58 kcal/kg/24 h (range 57–60). Other studies making measurements over 24-hour periods have produced similar figures, in the range 50–70 kcal/kg/24 h. If these figures are entered into equation (2):

$$\begin{array}{ccccccc} E_{\text{expend}} & = & E_{\text{BMR}} & + & E_{\text{activity}} & + & E_{\text{synthesis}} & + & E_{\text{thermoreg}} \\ 57-70 & & ? & & 10 & & 10-20 & & 10 \end{array}$$

a value for BMR of between 17 and 40 g/kg/24 h is obtained (Dauncey et al. 1977).

In order to estimate energy requirements, it is necessary to consider both the energy stored and energy excreted. In the study by Roberts et al. (1986), energy stored was 59 kcal/kg/24 h (which is about twice the figure for in utero energy deposition and substantially higher than ideal estimates for preterm infants, owing to the increased fat deposition seen postnatally). Energy losses in the stools have been estimated to be around 10–30 kcal/kg bodyweight, but massive losses may occur (well in excess of 50% of intake) in sick babies with an immature gut. If these figures are entered into equation (1):

$$\begin{array}{ccccccc} E_{\text{intake}} & = & E_{\text{stored}} & + & E_{\text{expend}} & + & E_{\text{excreted}} \\ & & 59 & & 57-70 & & 10-30 \end{array}$$

the required intake would be between 126 and 159 kcal/kg/24 h. This is slightly higher than the range recommended by ESPGHAN of 110–135 kcal/kg/24 h for healthy, growing preterm infants with adequate protein intake, and the 110–130 kcal/kg/24 h recommended by the recent international panel of experts for the stable preterm infant, although similar to their recommendations for ELBW infants (130–150 kcal/kg/24 h).

Water (see Ch. 18)

Water is a major nutrient (for review, see Wharton 1987). However, the quantity deposited in growth (around 10 ml/kg/24 h by preterm infants, for instance) is minute compared with water turnover. Clearly, in sick babies it would be impossible to allow nutrient intakes to vary in parallel with water requirement, and water must be treated as an 'independent variable'.

Nucleotides

There has been increasing interest over the last decade in the role of nucleotides in infant nutrition (Yu 2002). Breast milk contains at least 13 different nucleotides, accounting for up to 20% of non-protein nitrogen (Janas and Picciano 1982). Cow's milk has lower levels, accounting for about 5% of non-protein nitrogen, and a different nucleotide profile. Nucleotides are structural components of nucleic acids and therefore essential elements of the energy transfer system. They are assumed to play an important role in carbohydrate, lipid, protein and nucleic acid metabolism, and to act as modulators of many physiological processes, including immunity; it has been suggested that they are one of the anti-infective agents in breast milk, responsible for the lower levels of infection reported in breastfed infants. There is good evidence for the role of dietary nucleotides in animals (for example, enhancing T-cell function, and improving intestinal growth and maturation in weanling rats).

A variety of short-term effects have been reported for nucleotide-supplemented formulas in infants, including an alteration in the bowel flora following supplementation, with a predominance of lactobacilli as seen in the breastfed infant (Gil et al. 1986). There is also some evidence on the effect of nucleotide supplementation on clinical outcome in infants; a recent systematic review and meta-analysis examining the immune response to nucleotide-supplemented formulas identified 15 eligible randomised trials and concluded that infants fed nucleotide-supplemented formulas showed a better antibody response to immunisation; and fewer episodes of diarrhoea than infants fed unsupplemented formula or breast milk (Gutierrez-Castrellon et al. 2007). The EU Directive currently permits the addition of nucleotides to infant formulas for term infants up to a maximum concentration of 5 mg/100 kcal.

Macrominerals (Tables 16.1–16.3)

Sodium, potassium and chloride

Calculation of desirable intakes of sodium, potassium and chloride requires knowledge of renal function (see Ch. 18).

Preterm infants' requirements

Sodium

Major adjustments in body sodium occur in the neonatal period: massive renal losses of up to 10 mmol/kg/24 h or more can occur in the first week and may be independent of intake. It is impossible to predict accurately sodium needs in the early neonatal period, and in very small and sick infants, regardless of diet, plasma sodium should be monitored and hyponatraemia of <133 mmol/l, and certainly <130 mmol/l, should be corrected.

Preterm breast milk has a higher sodium content (>10–20 mmol/l during the early weeks of lactation) than mature donor milk (about <6 mmol/l). Hyponatraemia has been noted in preterm infants fed human milk; it is more severe in those fed donor milk. Intakes from donor milk and preterm milk, providing around 1 and 2 mmol/kg/24 h, respectively, during the first month, are often inadequate, and Aperia et al. (1982) have recommended 3 mmol/kg/24 h.

The high sodium content of modern preterm formulas is usually only required in the early neonatal period. After that, the excess sodium needs to be excreted. However, in a large randomised study (Lucas et al. 1988), preterm neonates fed on a formula providing 3.6 mmol/l did not have an increased risk of hypernatraemia, compared with those fed standard formula or breast milk (providing under half the sodium intake), and 13–16 years later did not show any elevation in blood pressure (Singhal et al. 2001).

Potassium and chloride

In general, human milk and the available adapted formulas provide adequate potassium and chloride to meet intrauterine accretion rates of 0.9 and 0.7 mmol/kg/24 h, respectively (Wharton 1987).

Calcium and phosphorus (Table 16.4)

Term infants

Calcium is less well absorbed from cow's milk than from human milk. However, in spite of the high levels of calcium and phosphorus in cow's milk, the relatively higher phosphorus intake has in the past resulted in hyperphosphataemia, hypocalcaemia with

Table 16.3 Trace metals

	PHYSIOLOGY	DEFICIENCY STATES
Iodine	Well absorbed, concentrated in thyroid gland, incorporated in thyroxine and tri-iodothyronine. Excess is excreted in urine	Endemic goitre in areas where human milk is deficient; soy formulas are iodine-deficient and are usually supplemented
Zinc	Present in a large number of metalloenzymes, including alkaline phosphatase and carbonic anhydrase. Required for insulin activity. Absorption partly by active transport. Bioavailability influenced by diet: poor absorption from diets of plant origin. Nadir in plasma zinc at around 2–3 months. Infants fed by total parenteral nutrition and those with gut disease are especially liable to clinical deficiency	Acrodermatitis syndrome. Delayed diagnosis if signs mistaken for ‘nappy rash’ of another aetiology NB may be inherited as a rare autosomal recessive disorder). Also mild deficiency in infancy, or later, may be associated with reduced growth, loss of appetite, impaired taste acuity and perhaps pica. Impaired immune responses, poor wound healing
Copper	Copper-containing enzymes include cytochrome oxidase, tyrosinase and uricase; required for iron utilisation, myelinisation and connective tissue formation. Absorption: stomach and small intestine. Stored in liver and muscle, attached to caeruloplasmin	See text
Manganese	Role: found in mitochondria, required for carbohydrate metabolism; actively absorbed in duodenum. Transport protein: transmanganin, a specific β -globulin. Excretion is largely biliary	No deficiency state described in human infants
Chromium	Role: potentiates insulin-induced glucose uptake. Poorly absorbed Transported by transferring. Body stores: low	In one study, diabetic glucose tolerance tests were corrected in infants with kwashiorkor
Fluoride	Enters bone and teeth, increasing their hardness. Supplementation is not recommended currently during the first 6 months	Dental caries. Excess: fluorosis, including rotting of teeth
Molybdenum	Present in xanthine oxidase. Active transfer across the placenta	No deficiency disease clearly recognised in human infants
Selenium	Role: antioxidant – cofactor for vitamin E	Deficiency not defined in neonates but described in children and adults living in the Keshan province of China: generalised myopathy with cardiac failure and haemolytic anaemia. Possibly occurs in preterm infants on unsupplemented long-term parenteral nutrition
Cobalt	Cobalt is a component of vitamin B ₁₂ and may not be needed independently of B ₁₂ requirement	

convulsions (see below), and other complications such as dental hypoplasia (Stimmler et al. 1973). Moreover, the high phosphorus content in unmodified cow's milk may also induce hypomagnesaemia, and, in some cases of neonatal tetany, convulsions can only be alleviated by administration of magnesium. Current recommendations for calcium and phosphorus are shown in Table 16.1.

Preterm infants' requirements

Considerable attention has been focused on the calcium and phosphorus requirements of LBW infants (Wharton 1987) stimulated by the high incidence of metabolic bone disease seen in this population (see Chapter 34 part 4).

Magnesium

The recommended intake for term infants is given in Table 16.1, and the physiology outlined in Table 16.3. Body magnesium content, largely in bone, rises rapidly in the third trimester, so that

preterm infants are born with low reserves. In preterm infants, net magnesium absorption in the first week is about 50% and is largely independent of vitamin D. Magnesium deficiency may impair calcium homeostasis. Atkinson et al. (1983) showed that infants fed on preterm milk (2.5–3.0 mg magnesium per 100 ml) failed to retain this element at intrauterine accretion rates, and showed evidence of falling reserves; in contrast, a formula-fed group receiving two to three times more magnesium retained it at a somewhat greater rate than in utero. In infants fed human milk, dietary supplementation with phosphorus improves magnesium retention by reducing urine losses.

Iron

Term infants

Iron stores at birth are influenced by gestation, birthweight and the extent of the placental transfusion at delivery. Healthy breastfed infants absorb iron well from human milk and usually maintain

Table 16.4 Digestion, physiological role and deficiency states of calcium, phosphorus and magnesium

	DIGESTION	PHYSIOLOGICAL ROLE	DEFICIENCY STATES
Calcium	Absorption by both passive and active transport: Ca, Mg-ATPase facilitates uptake into the mucosal cells, where a calcium-binding protein is induced by vitamin D. 20–60% retention, according to diet (better with human milk) but increased by vitamin D and parathormone and reduced by complexing with dietary fat, phosphate and phytates. Part bound, e.g. to protein, part free in plasma	Bones are major stores. Also required for cell membrane function, neuromuscular activity, clotting and a wide variety of cellular functions	Tetany, bone demineralisation, arrhythmias, paralytic ileus, fits
Phosphorus	70–95% absorption, increased by vitamin D, reduced by insoluble intraluminal complex formation, e.g. with phytate or if excessive calcium salts added. Commonly elevated in plasma in the neonatal period in cow's milk formula-fed term infants; nadir in preterm infants at 1–2 weeks	Bone mineralisation, ATP, DNA, RNA, phospholipids and many other biological roles	Rickets is rare in full-term newborns. Phosphate deficiency syndrome may arise, particularly in infants fed by total parenteral nutrition: listlessness, poor feeding, rapid shallow breathing, muscle weakness, impaired oxygen release from haemoglobin, bone disease, nephrocalcinosis
Magnesium	Some transport mechanisms may be shared with calcium: absorption increased by vitamin D and parathormone and decreased by steatorrhoea and phytates. High fetal plasma levels, which may fall after birth	Stored in bone. Important intracellular cation, muscle contraction, cofactor for carbohydrate, protein and energy metabolism	Weakness, poor feeding, failure to thrive, paralytic ileus, calcium-resistant tetany, fits, apnoea

normal iron stores during the first 4–6 months. However, the bioavailability of iron in cow's milk (especially) and cow's milk formulas is much less than in human milk. The EC Directive (European Commission 2006) recommended that formulas used from birth should, if iron is added, contain 0.18–0.9 mg/100 ml (Table 16.1).

Preterm infants' requirements

A 1.0-kg fetus contains 64 mg iron (Widdowson and Dickerson 1964), and this increases subsequently in utero at a rate of 1.8 mg/kg/24 h. About 25% of iron is stored in the liver as ferritin, and most of the rest is present in haemoglobin. After birth, therefore, a 1.0-kg infant only has sufficient iron to synthesise about 18.0 g haemoglobin (3.4 mg iron per gram haemoglobin), and since the iron content of human milk is 40 µg per 100 ml or less (providing 80 µg/kg/24 h fed at 200 ml/kg/24 h), preterm infants fed human milk will eventually develop an iron-deficiency anaemia without supplementation.

Iron stores usually remain adequate during the first 6–8 weeks, and iron supplementation at this stage has no influence on anaemia of prematurity. By around 12 weeks, iron stores become depleted in unsupplemented infants, and iron-deficiency anaemia develops. Intakes of 2.0–3.0 mg/kg/24 h have been shown by several groups to prevent such anaemia. However, variations in local practice regarding blood sampling, transfusion and use of erythropoietin treatment will influence iron requirements.

It is recommended that preterm infants receive a supplement of 2–3 mg/kg/24 h of iron, starting between 2 and 6 weeks of age (2–4 weeks in ELBW infants) and continuing until 12 months, or until

full mixed feeding provides an adequate iron intake. However, this should be adjusted according to blood transfusions and the use of erythropoietin in individual infants. A trial of high (20.7 mg/l) versus normal (13.4 mg/l) iron formulas in preterm infants found no difference in weight gain or development at 12 months post-term; however, the higher iron group had higher glutathione peroxidase concentrations, lower plasma zinc and copper levels and more respiratory tract infections, suggesting possible adverse effects from the higher intake (Friel et al. 2001).

Recombinant human erythropoietin (r-HuEPO) is occasionally used in preterm infants to reduce the requirement for blood transfusion. Studies have demonstrated (Shannon 1995) that infants treated with r-HuEPO require higher amounts of iron – up to 6 mg/kg/24 h – and that this should be initiated at the same time as the r-HuEPO.

Trace metals

Summaries of the physiological roles and the consequences of deficiency are shown in Table 16.3, and recommended intakes for term infants in Table 16.1.

Zinc

Zinc has been found in over 70 metalloproteins, mostly enzymes, including both DNA and RNA polymerase; it plays a critical role in cell replication and growth (Wharton 1987).

Zinc accumulates in the fetus during the last trimester at around 250 µg/kg/24 h. The amount of zinc provided by 200 ml of human

milk per kilogram per day falls from 1650 µg on the first day of lactation to 160 µg after 4 months. Therefore, human milk collected during the early (but not later) months of lactation theoretically provides enough zinc to meet in utero accretion rates. Zinc in banked donor milk should be adequate, although redistribution and alterations in the zinc-binding pattern during processing in human milk banks with an increase in the fat fraction and decrease in the whey fraction might reduce zinc bioavailability. [Dauncey et al. \(1977\)](#) found that preterm infants fed human milk did not achieve positive zinc balance until after 40 days of age.

Zinc deficiency has been described as a late sequel (2–4 months) of preterm birth ([Reifen and Zlotkin 1993](#)). These infants develop a syndrome very similar to acrodermatitis enteropathica, with growth arrest, irritability, anorexia, alopecia, diarrhoea, vesiculopustular lesions of the hands and feet, and the characteristic perioral, facial and perineal dermatitis; plasma zinc levels, though not necessarily helpful, are usually <35 µg/100 ml (5.4 mmol/l) (normal: 70 µg/100 ml). Infants respond rapidly to oral zinc sulphate (providing 1.0–3.5 mg zinc per day).

The EC Directive guidelines recommend a zinc concentration of 300–1060 µg/100 ml formula for term infants, and the [ESPGHAN \(1987\)](#) Committee on Nutrition recommended a daily intake of 1.1–2.0 mg/kg for preterm infants. The value of zinc supplementation for the long-term growth and development of infants born preterm or SGA requires further study.

Copper

Copper accumulates in the fetus during the last trimester at about 50 µg/kg/24 h; similar to iron and zinc, there is a hepatic store of copper at birth which is utilised during early infancy. The copper content of human milk falls from 600 µg/l during the first week of lactation to 220 µg/l by 5 months, but there is no evidence that human milk-fed infants require additional copper.

Several cases of copper deficiency have been described in infants born prematurely and fed on cow's milk-based formulas or copper-free parenteral nutrition solutions. The features of copper deficiency include psychomotor retardation, hypotonia, pallor and hypopigmentation, hepatosplenomegaly, X-ray changes of osteoporosis, blurring and cupping of metaphyses with subperiosteal new bone formation and fractures, and sideroblastic anaemia resistant to iron therapy. Neutropenia may also be present and the bone marrow shows vacuolated erythroid and myeloid cells, with iron deposition in the vacuoles. Several of these features are liable to develop when plasma copper falls below 20 mg/100 ml and caeruloplasmin below 5 mg/100 ml. Treatment with copper 0.6–0.8 mg/kg/24 h, given as 1% copper sulphate solution, is effective. A daily copper intake of 100–132 µg/kg is recommended for preterm infants.

Iodine

Iodine is found almost entirely in the thyroid, where it is incorporated into thyroglobulin and thyroid hormones. It is possible that a syndrome of transient hypothyroidism, seen in preterm infants, could be due to lack of iodine in iodine-deficient areas. The iodine content of breast milk is affected by maternal diet but is usually sufficient. The EC Directive guidelines suggest a minimum of 6.4 µg per 100 ml of formula.

Other trace minerals

Manganese, selenium, chromium and molybdenum are all essential elements, but no definite deficiency states have been described in

preterm infants fed human milk or cow's milk-based formulas ([Wharton 1987](#)); quantitative recommendations cannot be made on strong grounds. Manganese is found in very large unphysiological quantities in some formulas (especially soy-based ones), with values up to 100–1000 times those in human milk. It is not known whether these intakes are toxic, but there seems no basis for giving more than 5 µg per 100 ml of formula (human milk contains around 0.5–2.5 µg/100 ml).

Aluminium

Aluminium is not a nutrient – it has not been found in any metalloprotein, yet it has been added to drinking water (as a clarifying agent); it contaminates artificial formulas, especially soy formulas, which may contain 100 times the aluminium level of breast milk. However, the main source of exposure for infants, particularly those who are preterm, is aluminium contamination of some components of intravenous feeding solutions, notably calcium and phosphate salts, which have a high affinity for aluminium and encourage leaching from glass containers. A randomised trial in 227 preterm infants who received standard versus specially sourced low-aluminium parenteral nutrition solutions showed significant deficits in neurodevelopment at 18 months post-term of the order of a one developmental quotient point loss for each day of standard TPN received ([Bishop et al. 1997](#)). Follow-up of this cohort at age 13–15 years suggested that higher neonatal exposure to aluminium was also associated with lower bone mass ([Fewtrell et al. 2009b](#)).

It has been suggested that aluminium intake should be <5 µg/kg/day. However, [Poole et al. \(2008\)](#) calculated aluminium intakes of patients and found that even with the least contaminated currently available solutions it is impossible to meet the US Food and Drug Administration target of <5 µg/kg/day in patients under 50 kg; the situation is worst for those weighing <3 kg. Nevertheless, preterm and other sick infants clearly need parenteral nutrition for survival and to ensure optimal growth and development, and the risks of withholding parenteral nutrition would outweigh any possible adverse effects from aluminium exposure.

Vitamins

Clinical vitamin deficiency is rare in the neonatal period. Vitamin deficiency can occur in certain circumstances; these include maternal vitamin depletion, with reduced placental transport and low vitamin concentrations in breast milk, unsupplemented formulas, TPN, the use of unconventional non-milk-based diets, parasitic infestation, neonatal gut and biliary disease, and prematurity.

Optimal intake levels for many vitamins have not been determined in human infants. Broadly, vitamin intakes from breast milk have been taken as a guide ([Table 16.1](#)), but excess supplementation in formulas is usually employed in order to compensate for losses during preparation and storage and lower bioavailability. There is no clear evidence showing detrimental effects of excess vitamin supplementation, except for vitamins A and D, though it has been suggested that excessive vitamin E intake may interfere with wound healing and iron status.

The physiological roles of vitamins and clinical consequences of deficiency are summarised in [Table 16.5](#).

Term infants

Current recommended levels for formula-fed infants are shown in [Table 16.1](#).

Table 16.5 Vitamins: physiology and diseases caused by deficiency (or excess)

	PHYSIOLOGY	DEFICIENCY (OR EXCESS)
Vitamin A	Retinyl esters are the main contributor to vitamin A activity in milk, though both cow's and human milk contain the retinal precursor beta-carotene. Partly emulsified by bile salts, partly hydrolysed by lipase and re-esterified to retinyl palmitate in gut mucosa. One-sixth of dietary carotene is converted into active vitamin A. Stored in liver. Secreted by liver into the bloodstream in association with retinal-binding protein: secretion of vitamin A is tightly regulated like that of a hormone. Required for the synthesis of rhodopsin and other retinal pigments: important for the development of epithelial cells (and therefore the maintenance of epithelial membranes). Degraded by light	Xerophthalmia, susceptibility to infection, keratinisation of mucous membranes, blindness. Excess, e.g. 18 000 IU/day or above: raised intracranial pressure, dry skin, loss of hair, brittle bones, irritability
Vitamin E	Placental transfer low. Liver stores may be low. Iron may interfere with absorption and activity. Polyunsaturated fatty acids increase E requirement. Role: antioxidant, prevents oxidation of unsaturated fats thereby increasing stability of cell membranes	Clinical disease states poorly defined. Reduces postnatal red cell haemolysis
Vitamin D	Absorptive mechanisms not fully investigated in human infant: bile salts may be required – absorbed into lymphatic system. Stored in adipose tissue and muscle with small amounts in skin and liver. Sunlight-induced synthesis in the skin from 7-dehydrocholesterol will be minimal in many neonates; active metabolites are 25- and 1,25-hydroxyvitamin D (25-OHD and 1,25-(OH) ₂ D): these act as steroid hormones. Principal role: the enhancement of calcium and phosphate absorption from gut and renal conservation of these elements of bones and teeth of over 4000 IU/day	Rickets, tetany. Maternal vitamin D deficiency may rarely result in neonatal rickets. Very small amounts of vitamin D in breast milk. Maternal insufficiency increasingly recognised, especially in darker-skinned individuals and groups who cover themselves for religious reasons – increased risk of deficiency in their infants with breastfeeding if no supplement given. Also important for the normal mineralisation. Excess: intakes may result in hypercalcaemia. At intakes greater than 10 000 IU/kg per day: ectopic calcification, failure to thrive
Vitamin K	Emulsified by bile salts. Synthesis by gut flora is much debated. Stores in liver are relatively small. Maternal deficiency predisposes to neonatal deficiency. Role: manufacture of clotting factors (including II, VII, IX and X) and bone metabolism	Haemorrhagic disease of newborn. Excess: haemolytic anaemia can be caused by the water-soluble analogue
Thiamine (B ₁)	Role: coenzyme in many enzyme systems: pathways involving acetyl coenzyme A	Anorexia, irritability, fatigue, oedema, heart failure, constipation, peripheral neuropathy
Riboflavin (B ₂)	Component of flavoenzymes: involved in electron transport processes, e.g. in energy metabolism, fatty acid oxidation. Degraded by light	Cheilosis, angular stomatitis, impaired fatty acid oxidation and iron economy
Niacin	Part of NAD–NADP system of Krebs cycle; involved in protein and fat synthesis. Dietary tryptophan will supply niacin: 60 mg tryptophan = 1 mg niacin	Diarrhoea, dermatitis, neurological disturbance
Pyridoxine (B ₆)	Role: modification of functional groups, especially in amino acid metabolism (decarboxylation, transamination, oxidation, desulphurylation)	Convulsion, dermatitis, weakness, anaemia
Vitamin B ₁₂	Coenzyme for methionine synthesis and indirectly for DNA synthesis, folic acid metabolism, conversion of methylmalonic to succinic acid	Pernicious anaemia, central nervous system damage
Folic acid	Role: enzyme systems taking part in one-carbon transfers in DNA, RNA, methionine and serine synthesis, needed for histidine utilisation. Synthesised by gut flora	Megaloblastic anaemia, retarded growth, gastrointestinal disturbance
Pantothenic acid	Roles: part of coenzyme A system, involved in energy and fat metabolism. Synthesised by gut flora	No dietary deficiency state described in humans
Biotin	Role: carboxylation reactions, especially concerned with fatty acid synthesis. Produced by gut flora	Possibly skin rashes
Vitamin C	Water-soluble. Absorbed in upper intestine. Not stored: excess excreted in urine. Maternal deficiency may result in neonatal deficiency. Intake from unsupplemented pasteurised cow's milk is minimal. Role: involved in collagen synthesis and in several aspects of amino acid metabolism: protects against hypertyrosinaemia and hyperphenylalaninaemia in newborn period; promotes conversion of folic acid to folinic acid, catecholamine synthesis, carnitine synthesis, iron absorption	Biochemical deficiency may arise in newborn period – overt scurvy rare below 3 months of age

Preterm infants' requirements (Table 16.2)

Preterm infants may have special needs for some vitamins because:

- they are born with low body stores, especially of the fat-soluble vitamins which normally accumulate during the third trimester
- they may have reduced absorptive capacities for some vitamins (e.g. vitamin E)
- they might benefit from 'pharmacological doses' of certain vitamins, e.g. vitamin E.

A brief account follows, summarising information about vitamins of particular importance (Wharton 1987; Tsang et al. 2005).

Vitamin A

Vitamin A is required for the synthesis of retinal pigments and for the development and maintenance of epithelial membranes. The active form, retinol, is transported in plasma, bound to retinol-binding protein (RBP). The commonly used unit for vitamin A is μg retinol equivalent ($\mu\text{g RE}$: $1 \mu\text{g RE} = 3.33 \text{ IU vitamin A}$). Synthesis of RBP usually occurs late in gestation, and plasma retinol and RBP concentrations are lower in preterm than in term infants (Shenai et al. 1981). RBP also has a lower level of saturation in premature neonates. These data suggest that preterm infants have low body stores of vitamin A and are therefore at risk of deficiency. Low vitamin A status has been associated with an increased risk of chronic lung disease.

There is insufficient vitamin A in human milk to support the needs of the preterm infant (approximately $120\text{--}180 \mu\text{g RE/l}$) and supplementation of human milk-fed preterm infants seems wise (see below). Vitamin A can be obtained from the diet in two forms: preformed vitamin A (largely retinol) and carotenoids (chiefly β -carotene). Although β -carotene is potentially a good, non-toxic source of vitamin A, the efficacy of retinol synthesis in preterm infants is uncertain and it is recommended that the vitamin A requirement is met by providing preformed vitamin A. The recommended intake is $400\text{--}1000 \mu\text{g RE/kg/day}$ or $1330\text{--}3330 \text{ IU vitamin A/kg/day}$. Vitamin A is light-degraded: 70% can be lost from human milk during a 3-hour enteral infusion into an infant under phototherapy lighting. Care must be taken to ensure that the principal source of vitamin A given to preterm infants is not light-exposed.

Several studies have been performed to assess whether large doses of vitamin A can reduce the incidence of chronic lung disease (see Chapter 27 part 3). Meta-analysis of eight eligible studies suggested that regular doses of vitamin A either intramuscularly (six studies) or orally (two studies) were associated with a reduction in death or oxygen requirement at 1 month and a reduction in oxygen requirement in survivors at 36 weeks' gestation, although the latter outcome was confined to infants with birthweight $<1000 \text{ g}$. Meta-analysis of three studies with data on retinopathy of prematurity suggested a trend towards reduced incidence in vitamin A-supplemented infants (Darlow and Graham 2007). A single study reported no difference in neurodevelopmental outcome at 18–22 months postterm. The authors suggested that whether clinicians choose to use repeated intramuscular injections of vitamin A, which are painful, should perhaps depend on the incidence of chronic lung disease in their unit, and recommended that the benefits, safety and acceptability of delivering vitamin A in an intravenous emulsion compared with repeated intramuscular injections should be assessed in future.

Vitamin D

The term 'vitamin D' is often used to refer to both vitamin D_2 , originating from the plant sterol ergosterol, and vitamin D_3 ,

the natural vitamin synthesised in the skin from 7-dehydrocholesterol. Vitamin D_2 (or D_3) is converted to 25-hydroxyvitamin D (25-OHD, calcidiol) in the liver, and thence into the active metabolite 1,25-dihydroxyvitamin D ($1,25\text{-(OH)}_2\text{D}$, calcitriol) in the kidney. A major function of $1,25\text{-(OH)}_2\text{D}$ is to increase calcium and phosphorus absorption from the intestine, but it also conserves these two elements by its action on the kidney.

Preterm infants may have greater requirements for vitamin D than infants born at term; they have lower stores at birth and greater demands for skeletal mineralisation, and although the vitamin D pathway is intact, it may not be fully developed at very low gestation. Requirements will be greater still where maternal vitamin D status is suboptimal – an increasingly recognised scenario. The dose normally recommended for full-term infants, 400 IU/day , is probably well in excess of requirements for normal babies. However, in preterm infants, doses of up to $800\text{--}1000 \text{ IU/day}$ have been recommended, with the aim of achieving circulating 25-OH vitamin D values $>80 \text{ nmol/l}$ (von Kries et al. 1999). These doses have been shown to increase calcium absorption; however it is important to remember that vitamin D is no substitute for calcium and phosphorus supplementation in the prevention of bone disease (see Chapter 34 part 4). The use of 1,25-OHD rather than vitamin D may seem logical, as in very small preterm infants absorption of vitamin D may be impaired by a small bile salt pool size and fat malabsorption. Nevertheless, the use of such active metabolites of vitamin D, and especially the more potent ones (for example, $1\alpha\text{-OHD}$), is experimental and potentially dangerous.

Vitamin E

Increased intakes of vitamin E, which is a powerful antioxidant, may be required to prevent haemolytic anaemia in preterm infants, especially those receiving a diet rich in PUFA or iron. (Polyunsaturated lipids in cell membranes are liable to oxidative damage, which may be enhanced by iron.) There has been much interest in the use of pharmacological doses of vitamin E in preterm infants, but a review including 26 randomised studies suggested that supplementation in preterm infants reduced the risk of intracranial haemorrhage but increased the risk of sepsis. In VLBW infants, vitamin E increased the risk of sepsis, and reduced the risk of severe retinopathy and blindness among those examined. The authors concluded that evidence does not support the routine use of vitamin E supplementation by the intravenous route at high doses or aiming at serum tocopherol levels greater than 3.5 mg/dl (Brion et al. 2003).

Human milk contains adequate vitamin E in relation to its PUFA content. The recommended intake for preterm infants is $2.2\text{--}11 \text{ mg } \alpha\text{-TE/kg/day}$ ($1 \text{ mg } \alpha\text{-TE} = 1.49 \text{ IU}$), but this should be adapted in relation to the amount of PUFA in the diet.

Vitamin K

Despite recent controversy over the optimum route for administration and the dose required, vitamin K should be given routinely to all newborn babies as a prophylaxis against vitamin K-deficiency bleeding (VKDB). When given orally to breastfed infants, repeat doses are required to avoid the risk of intracranial bleeding from late VKDB. A Danish group reported that 12-weekly oral doses of 1 mg are completely effective, even in infants with liver disease (Norgaard-Hansen and Ebbesen 1996). However, von Kries et al. (1999) reported that not all cases of late-onset VKDB were prevented by three doses of oral vitamin K. The situation in sick term or preterm babies is not controversial: all such infants should receive $0.5\text{--}1.0 \text{ mg}$ of vitamin K parenterally on the first day.

Folic acid

Folic acid dosages for preterm infants vary considerably. In a large randomised study, [Stevens et al. \(1979\)](#) were unable to demonstrate differences in growth between LBW infants given either a supplement of 100 µg of folic acid per day (from 3 weeks to 12 months) or a formula containing only 3.5 µg folic acid per 100 ml (similar to human milk), and no infant became anaemic. More recently, however, [Worthington-White et al. \(1994\)](#) showed that formula-fed preterm infants who received supplemental folate for the first 6 months (100 µg/24 h) had higher serum folate concentrations and a significantly reduced fall in haemoglobin over the study period. [Haiden et al. \(2006a\)](#) randomised 64 preterm infants (birthweight 801–1300 g) receiving erythropoietin and iron treatment to treatment with either vitamin B₁₂ and folate (100 µg/kg/day) or a lower dose of folate (60 µg/kg/day). Infants in the treatment group showed enhanced erythropoiesis with a reduced fall in haemoglobin. In a second study, ELBW infants (birthweight <800 g) randomised to combined therapy with erythropoietin, iron, folate and vitamin B₁₂ had a significantly lower requirement for transfusion than control infants ([Haiden et al. 2006b](#)). An intake of at least 100 µg folate/24 h seems prudent for all LBW infants until 40 weeks' postconceptional age.

Vitamin C and pyridoxal phosphate (B₆)

Vitamin C has been shown to prevent hypertyrosinaemia and hyperphenylalaninaemia in LBW infants, especially those on high protein intakes. In view of this and the low vitamin C levels of unsupplemented preterm infants, a supplement is recommended (see below).

Supplementary B₆ might also be expected to improve protein utilisation, in view of its role as a cofactor in amino acid metabolic pathways; B₆ intake should be related to protein intake.

Riboflavin (B₂)

Most human milk-fed preterm infants develop biochemical evidence of riboflavin deficiency if they have received no supplement after the first week ([Lucas and Bates 1984](#)). This problem is compounded by the massive destruction of riboflavin by light when milk is handled in neonatal units. Early biochemical riboflavin deficiency has been shown to be prevented using a preterm formula containing 180 µg riboflavin per 100 ml, or by using a riboflavin-containing multivitamin preparation ([Lucas et al. 1987](#)). The recommended intake for preterm infants is 200–400 µg/kg/day.

Part 2: Feeding the full-term baby

Mary Fewtrell Alan Lucas

Breastfeeding

Breastfeeding is a complex physiological event: indeed, the term itself could be regarded as a misnomer, since ‘feeding’ is only one of several physiological processes that occur when a newborn infant is put to the breast. These processes can be summarised as follows:

- provision of nutrients
- provision of immunological and antimicrobial protection
- induction of adaptive events that equip the infant for extrauterine nutrition
- the passage of non-nutritive factors (other than antimicrobial ones) from mother to infant, e.g. breast milk hormones and growth factors
- provision of digestive enzymes, e.g. milk lipases
- effects on the mother, e.g. contraceptive role
- facilitation of mother–infant bonding
- ‘programming’ effects on long-term health.

Nutritive aspects of human milk

Human milk does not have a constant composition, and significant changes take place during the course of lactation, diurnally and during each feed. Uncertainty over the precise dietary intake of breastfed infants poses a major problem for nutritional science. In [Tables 16.6 and 16.7](#), the composition of average mature human milk is tabulated ([DHSS 1977](#)) together with the composition of unmodified cow’s milk.

Protein

The protein content of milks of mammalian species appears to be related to the postnatal growth rate of the infant ([Bernhart 1961](#)). Human infants have especially slow postnatal growth rates compared with many other mammals, and the protein content of human milk is correspondingly very low. Previously, the protein

content of mature human milk may have been overestimated, because of its high content of non-protein nitrogen: a realistic figure is 1.0 g/100 ml, compared with 3.5 g/100 ml in cow’s milk.

The two main classes of protein in milk are whey and casein. Human milk is whey-predominant (around 60% of total protein). Cow’s milk, however, is casein-predominant, with only 20% whey. In human whey, α -lactalbumin is the dominant protein, followed by lactoferrin. In contrast, the major whey protein in cow’s milk is β -lactoglobulin, which is absent from human milk and may be antigenic when fed to human infants. α -lactalbumin is present in cow’s milk, but lactoferrin occurs in only small amounts. Whey proteins have a high nutritive value for human infants; their essential amino acid content is high. It is now possible to prepare bovine milk whey fractions high in α -lactalbumin and lower in β -lactoglobulin, and there is some evidence that their addition to infant formulas may allow the total protein content to be lowered, resulting in a slower pattern of weight gain, more like that of a breastfed infant (see [Ch. 16.1](#)). Caseins may precipitate at low pH, forming a ‘curd’ in the infant’s stomach, and this has led to the widespread belief that casein-dominant formulas may be more satisfying for hungry infants. Human milk casein yields a softer, more flocculent curd than cow’s milk casein.

Human milk has a cysteine content about twice that of cow’s milk and a methionine/cysteine ratio that is seven times less than cow’s milk. In view of the late development of cystathionase (which converts methionine to cysteine), cysteine may be an essential amino acid in the newborn, and it has been suggested that the high cysteine content of human milk is biologically advantageous. In addition, the relatively low content of tyrosine and phenylalanine in human milk may be related to the newborn infant’s limited capacity to metabolise these amino acids.

The non-protein nitrogen content in human milk is unusually high – about 25% of the total, compared with 6% in cow’s milk. It consists of free amino acids, urea, creatinine, creatine, uric acid and ammonia. Clearly, free amino acids must be included with protein from a nutritional point of view; it is unknown whether other

non-protein nitrogen fractions have nutritional value (Carlson 1985). The free amino acids in human milk include taurine, which is present in significantly higher amounts than in cow's milk. During early lactation, milk protein content is much higher than in mature milk (Fig. 16.3). The falling protein content could represent an adaptation to the infant's decreasing protein requirements, or simply reflect the maturation of the mammary gland.

Energy

Published values for the energy content of breast milk (obtained unphysiologically as expressed breast milk) of around 70 kcal/100 ml have been challenged. Using the doubly labelled water method, which avoids milk sampling, Lucas et al. (1987) suggest that a figure close to 60 kcal/100 ml is realistic. Most formulas still have significantly higher energy contents than this (see below).

Fig. 16.3 Concentration of lactose, total nitrogen and non-protein nitrogen in human milk during the course of lactation.

18:2	13.0	1.6
18:3	1.4	1.8

Fat

The fat content of milk from different mothers is very variable, and in an individual usually increases during early lactation (1–2 weeks) and later declines. (Indeed, with the exception of lactose and lysozyme, most breast milk nutrients, including minerals and vitamins, decline after the first 2–3 months of lactation.) The fat concentration rises markedly during a feed, from around 2.1 g/100 ml to 4.1 g/100 ml (Lucas *et al.* 1980).

Cow's milk and human milk have similar fat contents and most of the lipid is triglyceride (98%); the principal difference is the pattern of fatty acids (Table 16.8). Human milk fatty acid profiles are, however, markedly influenced by diet. Vegetarians, for instance, consume more long-chain fatty acids than those on a mixed diet, and the amount of certain long-chain polyunsaturated fatty acids, notably docosahexaenoic acid, is markedly affected by the amount of fish and marine products in the maternal diet. Human milk has

a higher proportion of unsaturated fatty acids than cow's milk and a greater concentration of the essential fatty acids. Unlike cow's milk, fatty acids in human milk are esterified to glycerol predominantly in the 1 position, which improves their absorption.

Breast milk lipids occur as globules ranging in size from 1 to 10 microns, emulsified in the aqueous phase of milk (Jensen 1996). These globules consist of non-polar core lipids (such as triglycerides and cholesterol esters) covered with bipolar materials (including protein and phospholipids) which constitute the milk lipid globule membrane. The latter prevents the globules from coalescing and presents a large surface area for the action of lipolytic enzymes.

Carbohydrate

Lactose is present in higher concentrations in human milk (7 g/100 ml) than in cow's milk (4.7 g/100 ml). Lactose enhances calcium absorption from the gut, promotes the growth of lactobacilli and may help to create a favourable gut flora that protects against gastroenteritis.

Minerals

All major minerals are present in higher concentrations in cow's milk than in human milk (Table 16.7); with the higher protein content of cow's milk, they account for its high renal solute load. The amount of sodium in cow's milk is regarded as excessive for the human infant. However, early human milk has a high sodium content which may be 10 times that seen in mature milk. The raised phosphate/calcium ratio in cow's milk has been implicated in neonatal hypocalcaemia (see below).

Trace metals

The major trace metal concentrations in mature human and cow's milk are shown in Table 16.8. Zinc concentrations in mature human milk are rather less than those in cow's milk, whereas the reverse is the case for copper; cow's milk has substantially greater magnesium content. Copper, iron and zinc are present in higher concentrations in human colostrum than in later milk. However, the comparison of levels of trace nutrients in different milks is of less relevance than the bioavailability of these elements. There is good bioavailability of iron and other minerals from human milk. In cow's milk, iron and zinc are less available, the latter being bound to high-molecular-weight fractions.

Vitamins

In the west, vitamin deficiencies are generally rare in fully breastfed infants when the mother is well nourished. Vitamins K and D, however, require special consideration.

Vitamin K

Levels are low in breast milk (0.4–2.8 µg/ml), though they are higher in colostrum (0.8–4.8 µg/ml). In contrast, non-supplemented formulas usually contain around 6–11 µg/ml and supplemented formulas up to 100 µg/ml. Parenteral prophylaxis at birth with 1 mg vitamin K is effective against vitamin K-deficiency bleeding in breastfed infants (Ch. 30). There is still debate about the most suitable oral regimen, although repeated doses are considered necessary (Ch. 30).

Vitamin D

In the human infant, cholecalciferol (vitamin D) is derived mainly from the skin, synthesised from 7-dehydrocholesterol under the influence of sunlight. Breast milk provides only about 10 IU of

vitamin D daily in winter and 20 IU daily in the summer, and water-soluble vitamin D is present only in trace amounts that have negligible activity. Healthy, exclusively breastfed (EBF) infants have adequate bone mineralisation in the first 16 weeks of life (Roberts et al. 1981) and maintain satisfactory serum levels of 25-hydroxycholecalciferol for at least 6 months (Birkbeck and Scott 1980), suggesting that vitamin D supplements during this period are unnecessary, at least in mothers who are themselves vitamin D-sufficient. However, rickets has been reported in association with prolonged breastfeeding (Mughal et al. 1999). Over the past few years there have also been reports of an increase in the incidence of rickets in children of South East Asian origin living in the UK, particularly those living at higher latitudes; many women in this group are themselves vitamin D-insufficient or deficient (Ashraf and Mughal 2002). Although it is recommended that all breastfed infants receive 280–400 IU vitamin D daily from the age of 6 months if consuming <500 ml/day of infant formula, and that 'at-risk' groups should start supplements before 6 months, this frequently does not happen in practice, and there have been calls for a renewed campaign to raise awareness (Bolling et al. 2005; Leaf 2007). The situation regarding maternal supplementation was somewhat confused following the recent guidance from the National Institute for Health and Clinical Excellence that there is insufficient evidence to support routine provision of vitamin D to pregnant women (National Collaborating Centre for Women's and Children's Health 2003), whilst the Department of Health highlights pregnancy and lactation as high-risk periods and recommends a vitamin D intake of 10 µg (400 IU) per day; this is very unlikely to be met by diet alone since the average daily intake is around 3 µg/day.

Multivitamins

It has been recommended that in the UK children receive daily vitamin A (233 µg; 770 IU), vitamin C (20 mg) and vitamin D (7 µg) as a combined preparation from 6 months to 5 years (DHSS 1988) (available under the Healthy Start Scheme, although there have been problems with supply of these drops). However, in the most recent UK Infant Feeding Survey, conducted in 2005 (Bolling et al. 2005), only a tiny proportion of mothers were giving their babies vitamin supplements, increasing slightly by the age of 8–10 months. The proportion of babies receiving vitamins had also decreased since 2000, suggesting that mothers are not aware of the recommendations, and their importance for the health of their babies (Bolling et al. 2005). The American Academy of Pediatrics recommends that breastfed infants and those receiving <500 ml/day of infant formula should start vitamin D (5 µg/day) within the first 2 months of life (American Academy of Pediatrics 2003). This seems sensible, especially when there is doubt about the mother's dietary status.

Iron

The newborn term infant has an iron content of about 250–300 mg (75 mg/kg body weight). This iron will cover the needs of the term infant during the first 4–6 months of life and is why the iron requirements of healthy term infants during this period can be provided by human milk, which contains very little iron. Because iron stores are proportional to body mass at birth, babies who are small for gestational age may become iron-depleted well before 6 months. In the term infant, iron requirements rise markedly after age 4–6 months and amount to about 0.7–0.9 mg/day during the remaining part of the first year. These requirements are very high, especially in relation to body size and energy intake. In the first year of life, the term infant almost doubles its total iron stores and triples

its body weight. The increase in body iron during this period occurs mainly during the latter 6 months.

The breastfed infant's requirement for supplemental iron is controversial. The low levels of iron in breast milk (compared with those in supplemented modern formulas) are very well absorbed (around 80%, compared with about 4–6% from fortified formulas). Nevertheless, a small proportion of breastfed infants have lower iron stores at 6 months, and a greater proportion appear deficient at 9 months or later, than those fed iron-supplemented formula (Saarinen and Siimes 1979; Garry et al. 1981; Haschke et al. 1993). Iron status is influenced by several factors, including birthweight, maternal iron status during pregnancy and the placental transfusion received at delivery; indeed, a randomised trial showed that delayed clamping of the umbilical cord resulted in improved iron status at age 6 months (Chaparro et al. 2006).

Iron-deficiency anaemia is common in infancy and childhood. Although often asymptomatic, iron deficiency may be associated with adverse effects on cognitive outcome, although it remains uncertain whether the poor development of iron-deficient infants is due to poor social background or iron deficiency or a combination of the two factors (Grantham-McGregor and Ani 2001). In formula-fed babies, continued use of iron- and vitamin C-fortified formulas during infancy is effective in preventing iron-deficiency anaemia, but, in babies receiving breast milk plus weaning foods beyond 6 months, good nutritional advice is required with an emphasis on the provision of foods that are either rich in iron (for example, red meat) or iron-supplemented. Recommended intakes of iron between 6 and 12 months vary. The American Academy of Pediatrics recommends 11 mg/day, whilst the World Health Organization (WHO)/Food and Agriculture Organization give different figures depending on bioavailability: 6.2 mg/day for 15%, up to 9.3 mg/day for 10% and 18.6 mg/day for 5% (Joint FAO/WHO Expert Consultation on Human Vitamin and Mineral Requirements 1998).

Fluoride

Fluoride is not a nutrient, although epidemiological studies show its role in preventing dental caries. It has both systemic and topical actions. Systemically it acts on the teeth prior to eruption, being built into the structure of the enamel and making it resistant to decay. It also limits enamel demineralisation. Fluoride also acts topically by promoting remineralisation, possibly through antibacterial effects. The relative roles of systemic versus topical fluoride are still being debated. In areas where the water supply is fluoridated, infants consuming reconstituted formulas will have adequate intake, but in breastfed babies intake will inevitably be low. The British Dental Association (Dowell and Joyston-Bechal 1981) and the American Academy of Pediatrics have recommended that an intake of 0.25 mg fluoride should be achieved from 2 weeks to 2 years of age (available as drops), but emphasise the dangers (fluorosis) of exceeding this dosage from all sources combined. When water becomes the principal part of the breastfed infant's fluid intake, supplementation is no longer required if the water supply is fluoridated.

Nutritional adequacy of breast milk as the sole diet for healthy term babies

Maternal breast milk production rises to a peak in the third and fourth months after delivery, providing a mean of around 750–850 ml/24 h (more in boys than girls). The majority of EBF babies consume between 500 ml and 1200 ml per 24 h. By the end of this period, at intakes of 150 ml/kg the infant would consume 1.5 g/kg/24 h of protein and 85–105 kcal/kg/24 h (according to

which values for milk energy are accepted: see Lucas et al. 1987). Beyond 4–6 months, protein and energy intakes per kilogram body weight will fall as the infant grows, and eventually, without the introduction of complementary (weaning) foods, breast milk alone will no longer meet the infant's needs and complementary foods are required. However, the point at which this occurs is variable and difficult to define, even for populations (Reilly et al. 2005).

Data on the adequacy of 6 months' exclusive breastfeeding for meeting iron requirements have also been published. Consistent with findings from a randomised trial in Honduras, Chantry et al. (2007) reported that American infants EBF for 6 months are more likely to have a history of anaemia (adjusted odds ratio (OR) 0.20, 95% confidence interval (CI) 0.06–0.63) and low serum ferritin (OR 0.19, 95% CI 0.06–0.57) than those with full breastfeeding for 4–5 months. This finding is of concern given the risk of non-reversible long-term cognitive deficits associated with iron deficiency. Although the risk may be reduced by measures such as improving maternal iron status during pregnancy, delayed umbilical cord clamping and supplementing at-risk infants such as those born with low birthweight, in the absence of a screening policy it is likely that iron deficiency, which is usually asymptomatic, will be missed.

Optimal duration of exclusive breastfeeding

A systematic review of the optimal duration of exclusive breastfeeding was commissioned by the WHO in 2001, primarily to assess the effects on growth and health of exclusive breastfeeding for 6 months versus 3–4 months, with mixed breastfeeding (with complementary foods) thereafter (Kramer and Kakuma 2002). Sixteen studies meeting the specified inclusion criteria for the review were included: seven from developing countries and nine from developed countries. With the exception of two randomised trials conducted in Honduras, all studies were observational. The conclusions were as follows:

- Infants exclusive breastfeeding for 6 months show no evidence of weight or length deficits compared with those exclusive breastfeeding until 3–4 months, although larger sample sizes would be required to rule out small increases in the risk of undernutrition.
- Infants with suboptimal iron stores at birth who receive exclusive breastfeeding for 6 months without iron supplementation may be at risk of inadequate iron stores during infancy. This is more likely to occur in a developing country.
- Infants exclusive breastfeeding until 6 months have a significantly reduced incidence of one or more episodes of gastrointestinal (GI) infection during the first year. This finding is based primarily on an observational analysis of data from a large randomised trial of a breastfeeding promotion intervention in Belarus (Kramer et al. 2003). Because of its healthcare system and clean water supply, Belarus is regarded as a developed country in the context of infection risk. The incidence of GI infection during the first year was 7.4% (213/2862) in infants exclusive breastfeeding to 3–4 months, compared with 5.0% (31/621) in those exclusive breastfeeding to 6 months (OR 0.61, 95% CI 0.41–0.93). However, the difference in the proportion of infants hospitalised with GI infection did not differ significantly between groups (2.2% versus 1.8%, OR 0.75, 95% CI 0.38–1.04).

Following the WHO recommendation, in 2003, the UK Department of Health altered the advice for England and Wales in line with WHO recommendations, and suggested that mothers should exclusively breastfeed for the first 6 months before introducing solids. The advice to delay the introduction of solids until 6 months was

subsequently extended to formula-fed infants. Since 2001, four further studies from developed countries have suggested that more prolonged exclusive breastfeeding is associated with a reduced risk of GI or respiratory infection (Chantry et al. 2006; Paricio Talayero et al. 2006; Quigley et al. 2007; Rebhan et al. 2009); however, one UK study suggested that the increased risk associated with not being EBF was due to the introduction of infant formula rather than solid foods (Quigley et al. 2009). Against this, and of particular relevance for populations at risk of food allergy and coeliac disease, are emerging data suggesting that delaying the introduction of certain allergenic foods may actually increase the risk of subsequent disease (Prescott et al. 2008); this hypothesis is currently being tested in two UK randomised trials. With regard to gluten, the current consensus is that gluten is best introduced gradually alongside continued breastfeeding, and that the timing itself may not be so critical in determining the risk of disease (Agostoni et al. 2008).

Antibacterial aspects of human milk

Grulee's studies in Chicago in the 1930s, based on a 9-month period of supervised follow-up of 20 061 babies, provided convincing evidence of the anti-infective advantages of breastfeeding in the pre-antibiotic era (Grulee et al. 1935). With overall improvements in public health and obstetric and paediatric care in western countries, these major differences in infection rates have diminished dramatically, though much less so in developing countries. In developed countries, an increased morbidity (but not mortality) due to infection in bottle-fed babies is supported by recent evidence (Howie et al. 1990; Quigley et al. 2009), even when account has been taken of class differences in feeding preferences. Human milk may also have a protective effect against diarrhoea, respiratory tract infections and otitis media beyond the period of breastfeeding (Hanson 1998).

Immunoglobulins

The principal immunoglobulin in milk, secretory IgA, is present in the highest concentrations in the first few days postpartum. There is little evidence that absorption of the relatively low concentrations of IgG in human milk occurs. Secretory IgA is relatively resistant to low pH and proteolytic enzymes, and can be recovered from the stools of breastfed infants. It is likely that its protective effects are confined to the gut and perhaps to the respiratory tract. A wide variety of antibodies against viruses and bacteria and their toxins have been described in human milk, but their actions within the gut are not fully understood.

Other antimicrobial factors

Although all complement components have been demonstrated in human milk, their relatively low concentration, and the observation that heating milk up to 56°C for 30 minutes does not decrease its bacteriostatic action against *Escherichia coli*, has cast doubt on the anti-infective role of milk complement. Human milk is one of the richest sources of lysozyme, which is present in about 3000 times the concentration reported in cow's milk. In vitro, it acts with IgA to lyse *E. coli* and some salmonellae, but its role in vivo is not established.

The iron-binding protein lactoferrin may deprive gut organisms of free iron as a growth factor, and has been shown to be bacteriostatic and bacteriocidal in vitro, although its protective role in vivo is uncertain. Lactoferrin increases markedly in milk during lactation, and has received recent attention as a possible growth factor.

Other factors present in human milk, for example oligonucleotides and glycoconjugates, may act as receptors and divert

pathogens or toxins away from binding to the infant's pharynx or gut. Breast milk also contains nucleotides that may promote cell-mediated immunity (see [Chapter 16 part 1](#)), and prebiotic oligosaccharides that may promote the growth of a bifidogenic-dominant colonic microflora, which in turn protects the infant from enteropathogenic bacteria.

Nutritive aspects of antimicrobial factors

Previously it was believed that antimicrobial proteins, including IgA and lactoferrin, which constitute a significant proportion (30–40%) of milk protein, were not available for nutrition. [Prentice et al. \(1987\)](#) have challenged this view, suggesting that the great majority of these proteins are digested: by 6 weeks, only 1% of lactoferrin and 17% of secretory IgA is detected in the stools and 95% of total dietary protein could be regarded as nutritionally available.

Effects on gut flora

Recent work suggests that the factors that influence postnatal colonisation of the gut are complex, including delivery mode and environmental factors. However, studies performed since 1980 show relatively few differences in gut microbiota between breastfed and formula-fed infants. The most consistent differences are that clostridia, *Bacteroides* and Enterobacteriaceae tend to be more prevalent in formula-fed infants, whilst staphylococci tend to be more numerous in breastfed infants ([Adlerberth and Wold 2009](#)).

Cells in milk

Human milk is populated with macrophages, polymorphonuclear leukocytes and T and B lymphocytes; it has been calculated that the breastfed infant ingests as many viable leukocytes each day as he or she has circulating at any one time. The B lymphocytes contain cell lines that have synthesised IgA in the breast, but whether these cells survive for long enough in the infant's gut to carry out any further useful biological role is unknown. There is evidence that T cells in milk may transfer tuberculin sensitivity from mother to infant ([Schlesinger and Covelli 1977](#)), presumably mediated through lymphokines, which might have been secreted before the infant ingested the milk. There is no evidence that T lymphocytes are transferred across the gut in humans or participate in graft-versus-host disease. However, cells transferred from mother to infant may induce tolerance of maternal human leukocyte antigen status; previously breastfed infants who receive a renal allograft from their mother have less organ rejection ([Flores et al. 1993](#)).

Breast milk hormones

Possible 'messenger' substances in human milk

In recent years a wide variety of hormones and growth factors have been described in human milk ([Sack 1980](#); [Savino and Liguori 2008](#)). These include steroids, prolactin, thyroxine, gonadotrophins, melatonin, epidermal growth factor, prostaglandins and a number of adipokines and hormones known to be involved in appetite regulation and energy metabolism. It is an important question whether or not the lactating mother, in addition to providing nutrients and anti-infective factors, might also exert some control over neonatal metabolism, appetite and development through the mediation of chemical messengers and trophic factors secreted into her milk. More research is required in humans to confirm this hypothesis and determine whether interventions with these substances might be useful.

Enzymes in human milk

The bile salt-stimulated lipase in human milk may play a significant part in intestinal lipolysis ([Hamosh 1996](#)). Its presence may partly account for improved fat absorption from human milk compared with cow's milk, and for the observation that pasteurisation results in lower fat absorption from breast milk in preterm infants. Bile salt-stimulated lipase also has esterase activity, which may assist the digestion of breast milk retinyl esters.

Several other enzymes have been described in human milk. Breast milk amylase is identical in structure to the salivary enzyme, and probably compensates for the relatively slow postnatal development of the latter. Several proteases are also present, including trypsin, elastase and plasmin. However, it is doubtful whether they play an important role in the neonatal period because of the high antiprotease activity of human milk.

Other factors in breast milk

Babies may consume from breast milk a variety of substances which have no physiological value to them. Addictive drugs cause increasing concern. Some evidence suggests a need for caution over the regular use of alcohol by breastfeeding mothers: [Little et al. \(1989\)](#) initially showed that 1 unit of alcohol or more each day for the first 3 months was associated with reduced motor development scores in the infant at 1 year. However, in a more recent study of 915 infants from the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort, alcohol use during lactation was not associated with a deficit in motor skills at 18 months ([Little et al. 2002](#)).

Pesticide residues are officially monitored. Organohalogenes such as dioxins and polychlorinated biphenyls (PCBs) in breast milk are of current concern. These lipophilic chemicals are excreted in breast milk in 10–50 times the concentration in cow's milk or formulas, frequently exceeding accepted safety limits for cow's milk. They accumulate in fat over long periods, and some are highly toxic to skin, liver, and immune and nervous systems. They are also suspected carcinogens. Studies in infants to date have suggested that prenatal exposure to these substances may be associated with decreased psychomotor function, abnormal thyroid function tests (decreased triiodothyronine and thyroxine with elevated thyroid-stimulating hormone), and effects on immune status. However, despite relatively high levels of PCBs in breast milk, reflected in a threefold level of plasma PCBs in children at 2.5 years of age compared with formula-fed infants, no significant negative effects on outcome have been found. Indeed, a study of Dutch infants followed up to 6 years of age suggested that breastfeeding itself counteracts the adverse developmental effects of dioxins and PCBs ([Boersma and Lanting 2000](#)), whilst a more recent Dutch study of infants born in 2000 concluded that the current decreased exposure to polychlorinated dibenzo-p-dioxins/dibenzofurans and PCBs does not impair thyroid function of newborns and neurodevelopment of infants up to 24 months of age ([Wilhelm et al. 2008](#)).

Human immunodeficiency virus and other viruses in breast milk

Human immunodeficiency virus (HIV) has been found in breast milk in HIV-positive mothers, and there is good evidence that transmission to the breastfed baby occurs in up to 15% of cases ([Ch. 39](#)). It is known that exclusive breastfeeding is protective against postnatal transmission of HIV, compared with mixed breastfeeding; several studies have confirmed the increased risk of transmission of

HIV when solids are combined with breastfeeding during the first 6 months. Accordingly, exclusive breastfeeding for 6 months is the [World Health Organization's \(2008\)](#) recommendation to HIV-infected mothers for whom exclusive replacement feeding (that is, with infant formula) is not acceptable, feasible, affordable, safe or sustainable. In countries where formula-feeding is safe, including the UK, it is recommended that such mothers do not breastfeed.

Both hepatitis B virus (HBV) and hepatitis C virus (HCV) may be found in the breast milk of seropositive mothers, and transmission to the infant has been reported. However, most evidence suggests that breast milk is an uncommon route of infection ([Uehara et al. 1993](#); [Moriya et al. 1995](#)). Mothers who wish to donate breast milk are now routinely screened for HBV, HCV and HIV, and excluded if positive.

Cytomegalovirus is found in the milk of between 32% and 96% of seropositive mothers when polymerase chain reaction is used ([Hamprecht et al. 2001](#)), and breastfed babies of seropositive mothers show a higher rate of seropositivity at 1 year of age (70%) than those who are bottle-fed (30%) ([Minamishima et al. 1994](#)). This does not generally pose a problem for healthy term babies, but may do in those born preterm (see [Ch. 39](#)).

Maternal aspects of breastfeeding

Advice and assistance

The UK Baby Friendly Initiative (BFI) under the umbrella of UNICEF was set up in 1994 and aims to increase the incidence and duration of breastfeeding. The BFI has produced '10 steps to successful breastfeeding' for maternity services and a 'seven-point plan for the protection, promotion and support of breastfeeding' in community healthcare settings (see [Weblinks](#)). The BFI has also recently produced best practice standards for breastfeeding on neonatal units (see [Ch. 21](#) regarding storage and expression of breast milk). There are numerous documents about breastfeeding and other aspects of infant feeding aimed at parents and/or health professionals such as those produced by the Department of Health, the National Child-birth Trust, La Lèche League, and Bliss (the premature baby society). In 2008, Best Beginnings launched the DVD 'From bump to breastfeeding', which is being distributed to all pregnant women in the UK (see [Weblinks](#)).

Despite greater focus on increasing the incidence and exclusivity of breastfeeding in the UK, rates remain among the lowest in Europe. In the 2005 Infant Feeding Survey ([Bolling et al. 2005](#)), breastfeeding initiation rates were 78% in England, 70% in Scotland, 67% in Wales and 63% in Northern Ireland: an increase of about 5% since 2000. However, the rates fell sharply to 63% at 1 week, 48% at 6 weeks and 25% at 6 months. The prevalence of exclusive breastfeeding had not increased, with 65% of mothers exclusively breastfeeding at birth but only 21% at 6 weeks and <2% at 6 months. Nine out of 10 mothers who gave up breastfeeding within 6 months stated that they would have preferred to breastfeed for longer. Overall, among all mothers ceasing to breastfeed, the single largest factor behind cessation of breastfeeding was 'insufficient milk', with 39% giving this as a reason.

A recent review commissioned by the former Health Development Agency concluded that, when implementing interventions to increase breastfeeding initiation and continuation rates, each locality should consider the best package of interventions to address the diverse needs of its local population group(s) ([Dyson et al. 2009](#)). Effective evidence-based interventions included routine implementation of the UNICEF UK BFI across NHS hospital trusts; an appropriate mix of education and support programmes routinely delivered by both health professionals/practitioners and peer supporters in

accordance with local population needs; and changes to policy and practice within the community and hospital settings to support effective positioning and attachment, using a predominantly 'hands-off' approach, encouraging unrestricted baby-led breastfeeding, which helps prevent engorgement; and encouraging the combination of supportive care, teaching breastfeeding technique, sound information and reassurance for breastfeeding women with 'insufficient milk'.

Artificial feeding for the normal term infant

General considerations

The purpose of artificial feeding is to provide a satisfactory food for infants in situations where a substitute for breast milk is required. The 'ideal' artificial diet should:

- meet the nutrient needs of healthy infants
- be well tolerated without inducing metabolic stress or biochemical disturbance
- not result in short- or long-term morbidity.

In the early days of artificial milks, they frequently failed to meet any of these criteria – sometimes with serious consequences. Modern formulas come much closer to attaining these goals ([Table 16.6](#)).

Recommended dietary allowances for formula-fed infants

From a teleological point of view, breast milk should be the nutritional standard for formula-fed infants. Many of the current recommended daily allowances are based on the concentrations of nutrients in human milk. However, in constructing a formula from non-human milk components, account must be taken of: (1) the bioavailability; (2) the digestibility; and (3) the biological value of the nutrients, all of which may differ from those in human milk. Rather than attempting to replicate human milk, which in most respects is an impossible goal, there is increasing focus on aiming to achieve the outcomes seen in the breastfed infant.

Milk volume

Based on human lactational studies, fluid intakes of around 150 ml/kg/24 h are satisfactory for the first 3–4 months in formula-fed infants. However, this is only an approximate guideline: healthy infants fed on formula ad libitum (as with breastfed infants) will show considerable variations in intake in association with normal growth. There is increasing recognition that the milk intake of breastfed infants during the first few days of life is considerably lower than that of infants fed formula ad libitum during this period ([Casey et al. 1986](#); [Dollberg et al. 2001](#)). It is important that lactating mothers are aware of this if they are to have confidence in their ability to provide 'sufficient' milk for their infants. The role of these early differences in milk intake and growth, and potential consequences for later health, are under investigation.

Artificial formula

Unmodified cow's milk

'Doorstep' milk is not recommended for infants in the first 12 months in the UK. Problems that may be encountered with cow's

milk, or unmodified cow's milk formulas, include hyperosmolar dehydration associated with high renal solute load, hypocalcaemic fits associated with phosphate overload, casein curd obstruction, vitamin deficiency (e.g. rickets, scurvy) and iron-deficiency anaemia. These problems are rarely seen in infants fed modern formulas. Skimmed and semiskimmed milk should not be used because of their low energy and vitamin A contents. Indeed, the UK Department of Health recommends that fully skimmed milk should not be given before the age of 5 years (DHSS 1988).

Goat's milk

Goat's milk is not suitable for infant feeding because of its high solute load and low vitamin content. It is particularly deficient in folate, and severe megaloblastic anaemia may result if goat's milk is the sole feed.

Modern cow's milk-based formulas

Modern milk formulas have been extensively modified from their predecessors in their protein, lipid, electrolyte and trace nutrient composition. Table 16.7 shows the composition of the standard infant formulas available in the UK, and Table 16.8 the composition of follow-on formulas. There is no information on whether or not the more recent finer degrees of modification have resulted in significant benefits, but it seems reasonable on empirical grounds to manufacture products resembling human milk as closely as possible. The need for further 'humanisation' of infant formulas is still actively under investigation. Topical issues include lowering total protein content to, say, 1.2–1.4 g/100 ml (cf. 1.5 g/100 ml currently; Table 16.6); the addition of sources of long-chain polyunsaturated fatty acid (C20 or greater); and the addition of other factors found in human milk, including nucleotides (Ch. 39.1), oligosaccharides, probiotics, α -lactalbumin and bile salt-stimulated lipase.

Soya formulas

The problems encountered with earlier soya-based formulas have been largely overcome; formulas are now supplemented with methionine, taurine and carnitine, and contain adequate minerals to allow for losses due to phytate binding in the gut. They are able to support normal growth and bone mineralisation when used as the sole diet. However, some issues remain unresolved. Attention has been drawn to the potentially large amounts of plant oestrogen (phyto-oestrogen) that may be ingested by infants who are fully fed on soya formulas: studies have shown that infants fed soya formula have plasma concentrations of phyto-oestrogens hundreds of times higher than those fed breast milk or cow's milk formula (Setchell et al. 1997). However, a follow-up study of adults who had received either soya formula or cow's milk formula in infancy found no evidence of long-term effects of early soya exposure on either general or reproductive health (Strom et al. 2001).

Although many infants receive soya formulas because of suspected cow's milk allergy, it should be recognised that soya protein is itself potentially allergenic. Double-blind placebo-controlled challenges with soya milk in infants with proven allergy to cow's milk protein have suggested that around 5% of these infants are also intolerant of soya protein (Dean et al. 1993). In the UK, it is recommended that soya formulas should only be used following advice from a health professional.

Practical aspects of formula feeding (see Weblinks)

The following points need emphasising.

1. Attention to sterility is vital, since powdered infant formulas are not sterile products. The European Food Safety Authority's Scientific Panel on Biological Hazards concluded that *Enterobacter sakazakii* and *Salmonella* are the microorganisms of greatest concern. Although infections with these microorganisms from formula milks are rare in healthy infants, the risks can be reduced by following the guidelines which recommend using freshly boiled water, cooled to no less than 70°C, and making up formula fresh for each feed. The poor microbiological standards of drinking water that may be found in developing countries, among other factors, make formula feeding highly undesirable in this situation. Bottled water should be the same standard as water from the public supply, but some marketed waters are unsuitable for infants; for example, 'natural mineral water' may contain unacceptable levels of carbon dioxide, sodium, nitrate and fluoride (DHSS 1988).
2. For high-risk infants (preterm, low-birthweight and immunocompromised), ready-to-feed liquid formulas are recommended as these are sterile.
3. Correct reconstitution of feeds with accurate use of the scoops provided by manufacturers is vital. A systematic review concluded that errors in the reconstitution of infant formulas are widespread, with a tendency to overconcentrate, although underconcentration also occurred. This review also highlighted the range of different scoop sizes produced by manufacturers (Renfrew et al. 2003).

Breast versus formula

The relevant question for the medical profession is whether or not there are clinical grounds for wishing to influence parental choice. In the developing world, the evidence that breastfeeding has a major influence on infant mortality and morbidity is well established and the case for medical intervention is strong. In the developed world, the situation is rather different: in spite of considerable speculation on the benefits of breastfeeding, it has been harder to prove major detrimental effects of bottle-feeding. Comparisons between breast- and bottle-fed infants are almost exclusively epidemiological, as it is not possible to randomise infants to one feeding regimen or another, and potential confounding by factors that differ between breast and formula-fed infants, such as social class and circumstances, has made it difficult to evaluate published data on the differences between breast- and bottle-fed babies in their subsequent health and development. Data from both randomised and observational studies are summarised below.

Experimental studies

The Promotion of Breastfeeding Intervention Trial (PROBIT) (Kramer et al. 2001), a cluster-randomised study conducted in Belarus, involved more than 17 000 mother and term-infant pairs from clinics assigned either to standard practice or to an intervention modelled on the UNICEF BFI, which increased the incidence and exclusivity of breastfeeding. Infants from the intervention group had a significantly lower risk of developing both gastroenteritis and eczema during the first year of life. Further follow-up of this cohort at age 6 years has reported significantly higher cognitive scores with the intervention (Kramer et al. 2008), but no effect

on height, adiposity, blood pressure or child behaviour (Kramer et al. 2007).

Evidence for the benefits of breast milk has also come from a large randomised trial of diet during the neonatal period in preterm infants. Those who received human milk, whether mother's own or banked, were significantly less likely to develop necrotising enterocolitis or systemic infection, and showed better feed tolerance. More recently, longer term benefits have become apparent. The use of human milk was associated with lower blood pressure (Singhal et al. 2001), reduced insulin resistance (Singhal et al. 2004), a more favourable plasma lipid profile during adolescence (Singhal et al. 2003) and higher bone mass (Fewtrell et al. 2009).

Observational studies

Two recent systematic reviews and meta-analyses have examined data on the health effects of breastfeeding. Ip et al. (2009) concluded:

- A history of breastfeeding was associated with a reduction in the risk of acute otitis media, non-specific gastroenteritis, severe lower respiratory tract infections, atopic dermatitis, asthma (in young children), obesity, type 1 and 2 diabetes, childhood leukaemia and sudden infant death syndrome.
- There was no relationship between breastfeeding in term infants and cognitive performance after including studies that had measurements of maternal IQ.
- There were insufficient good-quality data to address the relationship between breastfeeding and cardiovascular diseases and infant mortality.
- A history of lactation was associated with a reduced risk of type 2 diabetes, breast and ovarian cancer in the mother.
- Early cessation of breastfeeding or no breastfeeding was also associated with an increased risk of maternal postpartum depression.

In a second review examining data on the long-term health effects of breastfeeding for the WHO, Horta et al. (2009) concluded that subjects who were breastfed experienced:

- lower mean blood pressure and total cholesterol
- higher performance in intelligence tests
- lower prevalence of overweight/obesity and type 2 diabetes.

Overall, these data suggest that there is sufficient evidence of clinical benefit to promote breastfeeding as the 'ideal' for term infants in developed countries. To help achieve this goal, better health education (starting at school) is required in order to promote a culture in which breastfeeding is regarded as the normal way to feed infants (see above). Nevertheless, while it is important to promote and protect breastfeeding, it is also necessary to ensure that the needs of bottle-feeding mothers are met, particularly as the majority of infants in countries such as the UK, even if exclusively breastfed initially, will receive some infant formula during the first year of life. A recent systematic review of the literature on parents' experiences of bottle-feeding found several consistent themes (Lakshman et al. 2009):

- Mothers who bottle-fed their babies experienced negative emotions such as guilt, anger, worry, uncertainty and a sense of failure.
- Mothers reported receiving little information on bottle-feeding and did not feel empowered to make decisions.
- Mistakes in preparation of bottle-feeds were common.

The reviewers concluded that inadequate information and support for mothers who decide to bottle-feed may put the health of their babies at risk. A variety of emotional benefits to the mother have been put forward for breastfeeding, but these may cease to be benefits if the mother has set her mind against feeding her baby this way.

Part 3: Feeding low-birthweight infants

Mary Fewtrell Sirinuch Chomtho Alan Lucas

General considerations

The principal matters to be decided when planning enteral feeding in low-birthweight (LBW) infants are which diet, which route of administration and what feeding schedule should be selected. Valuable short-term studies have been performed on preterm infant feeding, but only more recently have data become available on the longer term effects of early nutrition for later health and development. Information of this nature is critical in order to assess the value of current practice.

Choice of diet

A wide range of diets have been used for feeding LBW infants, including the following:

- human milk:
 - mother's own: 'preterm milk' (PTM)
 - banked donor milk (expressed breast milk or drip breast milk)
 - fortified human milk
 - human milk formulas (separated and reconstituted human milk)
- 'term' infant formulas:
 - cow's milk-based
 - soya-based
- special 'preterm' infant formulas

- parenteral feeding (see Ch. 17):

- partial
- total.

Human milk

There is major interest in human milk for feeding LBW infants, and the practice of encouraging mothers to provide milk for their own preterm infants has become widespread. The value of breast milk in neonatal intensive care needs critical appraisal.

Nutritional considerations

Unmodified human milk may not always meet the theoretical requirements of LBW infants for several nutrients, including:

- protein (especially when 'mature' donor milk is used)
- energy (especially donor drip breast milk)
- sodium
- calcium, phosphorus and magnesium
- trace elements, e.g. iron, zinc and copper
- certain vitamins (e.g. B₂, B₆, folic acid, C, D, E and K).

However, human milk does have theoretical nutritional advantages compared with formulas, including the composition and easier absorption of its fats and the bioavailability of certain trace metals. Formulas designed to meet the calculated nutrient needs of preterm

infants impose a greater renal solute load on the baby than that of human milk.

Infection and necrotising enterocolitis

In a large study, with randomised dietary assignments, [Lucas and Cole \(1990b\)](#) showed that preterm babies fed exclusively on formula had six times more confirmed necrotising enterocolitis (NEC) than infants fed exclusively on breast milk (fresh or pasteurised – but without the use of breast milk fortifiers) and three times the NEC rate of those fed formula in conjunction with breast milk. The authors suggested that using either raw maternal milk or pasteurised donor milk in the early diet of preterm infants might prevent about 500 cases of NEC each year in the UK. This finding was supported by a recent Cochrane systematic review of five randomised controlled trials (RCTs) comparing formula and donor breast milk (DBM) ([Quigley et al. 2007](#)). In a non-randomised analysis, [Schanler \(2005\)](#) reported that, compared with groups of infants fed DBM or preterm formula (PTF), those who received maternal breast milk had fewer episodes of late-onset sepsis and/or NEC and total infection-related events, a shorter duration of hospital stay and fewer Gram-negative organisms isolated from blood cultures than did the other groups. Most recently, [Sullivan et al. \(2010\)](#) reported the results of a randomised trial in which preterm babies receiving mother's own breast milk (MBM) were randomised to receive either a completely human milk-based diet, using pasteurised donor human milk-based fortifiers and/or DBM if there was insufficient MBM, or a conventional bovine milk fortifier and/or preterm infant formula. Babies who received the human milk-based diet had significantly lower rates of NEC ($p < 0.02$) and, especially, NEC requiring surgical intervention ($p = 0.007$). There was no difference between groups in growth or rates of late-onset sepsis. An RCT of feeding methods in babies at high risk of NEC because they had absent or reversed end-diastolic blood flow in the umbilical artery (the ADEPT trial) showed no difference in outcome whether feeds were initiated early or were delayed ([Leaf et al. in press](#)). Some babies took over a month to establish full feeds.

Allergy

There is a theoretical possibility that feeding the preterm infant with cow's milk proteins at a time when gut permeability may be increased ([Zachariassen et al. 2010](#)) could raise the chance of later cow's milk allergy. Indeed, [Lucas et al. \(1984b\)](#) showed that preterm neonates rapidly developed latent sensitisation to cow's milk. The feeding of human milk (versus formula) was associated with decreased intestinal permeability of preterm infants at 28 days of age ([Shulman et al. 1998a](#)). Many of the bioactive factors in human milk function at the level of the gastrointestinal tract to protect the infant from foreign antigens. At the 18-month follow-up of a randomised trial of early nutrition, [Lucas et al. \(1990a\)](#) found no overall difference in allergic reactions between infants fed formula or DBM, but in the subgroup of infants with atopy in one or more first-degree relatives, early formula feeding was associated with twice the incidence of subsequent allergic reactions compared with those in the exclusively human milk-fed group (for eczema the respective incidences were 41% and 16%).

Gastrointestinal 'tolerance'

Gastrointestinal 'tolerance' of human milk is greater than that of formulas. [Cavell \(1982\)](#) has shown that human milk passes through

Fig. 16.4 Days to attain full enteral feeds according to diet in over 300 preterm infants under 1850 g birthweight. Data are represented in centiles; the horizontal lines in the data bar for each diet represent, from bottom to top, the 5th, 25th, 50th, 75th and 95th centiles for the number of postnatal days to reach an enteral intake of 150 mg/kg/24 h.

the stomach faster than formula in preterm infants, and intestinal lactase activity (a marker of intestinal maturity) is greater in infants fed human milk compared with formula and greater in those fed early in life ([Shulman et al. 1998a, b](#)). It often takes substantially longer to establish full enteral feeding in infants fed formula: in a five-centre study, 95% of infants fed breast milk were on full feeds by 18 days, whereas the 95th centile for formula-fed babies was more than 40 days, owing to a proportion of infants in whom it was difficult to achieve feed tolerance ([Fig. 16.4](#)). These data have implications for the design of feeding regimens (see below).

Developmental scores

Preterm babies fed on their own MBM have been shown to have higher developmental scores at 18 months and higher IQs at 7.5–8 years than those fed on other diets, even after adjusting for a range of demographic, social and clinical factors that might confound this comparison ([Morley et al. 1988](#); [Lucas et al. 1992b](#)). At 15–16-year follow-up, the percentage of expressed breast milk in the neonatal diet correlated significantly with verbal IQ and white-matter volume (from magnetic resonance imaging) in males ([Isaacs et al. 2009](#)). Whether these findings reflect a failure to adjust for further (unknown) confounding factors, or whether fresh human milk has a beneficial effect on development, is an important question for investigation. The latter explanation is favoured by the observation that infants fed banked breast milk had higher developmental scores at 18 months than those fed term formulas, despite the lower macronutrient content of banked breast milk ([Lucas et al. 1994](#)). Developmental outcome in term small-for-gestational-age infants at 18 months was also better among those breastfed than among those fed 'term' or 'nutrient-enriched' formula ([Morley et al. 2004](#)).

Long-term cardiovascular health

Follow-up of adolescents born preterm and randomised to receive banked breast milk or PTF during the neonatal period has shown significantly lower blood pressure and a more favourable lipid profile in those who received human milk ([Singhal et al. 2001, 2004](#)). Breast milk-fed children had a low-density lipoprotein:high-density lipoprotein cholesterol ratio that was 14% lower than

formula-fed children, an effect size very similar to the 10–16% benefit in this ratio associated with breastfeeding reported in subjects born at term. The lower mean blood pressure seen in children who had received human milk (81.9 (SD 7.8) mmHg versus 86.1 (SD 6.5) mmHg) was seen whether fresh MBM or banked DBM was used. The average effect size seen in this study is larger than that produced by any non-pharmacological method of reducing blood pressure during adult life (weight loss, exercise, diet). Moreover, this magnitude of reduction in blood pressure in an adult population would be expected to reduce the prevalence of hypertension by 17%, the risk of cardiovascular disease by 6% and the risk of strokes and transient ischaemic attacks by 15%.

Interestingly, children who received human milk also had evidence of both lower insulin resistance (Singhal et al. 2003) and better arterial distensibility (an early marker of vascular disease) than children from the PTF group. These effects seemed to be mediated by growth predominantly during the first 2 weeks of postnatal life, and led to the growth acceleration hypothesis – that promoting growth early in the neonatal period may not be optimal for certain aspects of longer term cardiovascular health (Singhal and Lucas 2004) (see below).

Types of breast milk

The composition of breast milk depends on its source, the mode of its collection and on the postnatal and postconceptional age of the donor; it can be further modified by its subsequent treatment.

Preterm milk

The milk of mothers who have delivered preterm infants – so-called preterm milk or PTM – has a different composition from that of mothers delivered at term, with higher total nitrogen, protein nitrogen, immune proteins, total lipid, medium-chain fatty acids, energy, vitamins, some minerals (e.g. calcium, sodium), and trace elements (e.g. zinc, copper) and with a raised IgA content in early lactation (Schanler and Atkinson 2005). The reasons for these differences remain speculative but may relate to the low volume often produced by PTM donors (Lucas and Hudson 1984). Preterm colostrum may also have greater potential for preventing infection than term colostrum owing to its higher IgA, lysozyme, lactoferrin and living cells (Lawrence and Lawrence 2005). PTM is thus more suitable than term donor milk for feeding preterm infants, particularly in view of its higher concentration of protein. However, protein intakes from PTM are very variable, and by the second month of PTM production protein concentrations often fall to values at which theoretical needs would be met only by very high-volume intakes. PTM may be given raw to the mother's own infant, in which case antimicrobial components will remain intact. Neither microbiological examination nor pasteurisation is necessary in this situation, provided that the collected milk is refrigerated adequately and fed to the infant within 48 hours, or at most 72 hours, or if it is frozen.

Many mothers who elect at the outset to provide milk for their own infants, either totally or partially, fail to do so. In over 600 MBM-fed infants from several centres studied between 1982 and 1985, maternal milk constituted less than 50% of total enteral intake. A more recent study of 243 extremely low-birthweight (ELBW: gestational age 23–29 weeks, recruited from 1997 to 2001) babies from the USA found that around 27% of the mothers were able to sustain lactation to meet the needs of their extremely premature infants (Schanler and Atkinson 2005). Factors contributing to lack of success in producing sufficient PTM include

physical separation of mother and child, inadequate support, the inherent difficulty of maintaining the milk supply by manual or mechanical expression, lack of motivation and, not least, poor advice.

The difficulties faced by mothers trying to provide milk for their preterm infant must not be underestimated. They may need to express milk for a period of weeks or months in the absence of significant suckling stimulus and in the presence of a great deal of stress, a potent inhibitor of the milk ejection reflex. Simple measures have been shown to improve milk volume. These include increasing the frequency of expression (around six to eight times a day as a minimum), kangaroo care or skin-to-skin contact, relaxation tapes and avoidance of smoking. There is strong evidence that short periods of kangaroo skin-to-skin contact increase the duration of any breastfeeding for 1 month after discharge (risk ratio (RR) 4.76, 95% confidence interval (CI) 1.19–19.10) and for more than 6 weeks (RR 1.95, 95% CI 1.03–3.70) among clinically stable infants in industrialised settings (Renfrew et al. 2009).

The type of breast pump and mode of expression may also be important. Jones et al. (2001) showed that the use of breast massage prior to pumping and the use of simultaneous as opposed to sequential pumping both increased milk volumes in mothers using the Ameda electric breast pump, and that there was an additive effect of massage and simultaneous pumping. Recently, there has been some interest in the design of more physiological breast pumps – that is, using alternative strategies to simple suction, which is inherently unphysiological in human lactation (Fewtrell et al. 2001a). Pharmacological interventions have also been investigated. Some data suggest that use of dopamine antagonists to increase prolactin concentrations may improve milk production of preterm mothers experiencing lactation failure at or beyond 3 weeks postpartum, without substantially altering the nutrient composition (Campbell-Yeo et al. 2010). Oxytocin can theoretically enhance the let-down reflex, although a recent RCT did not show significant advantages over placebo in final milk production in preterm mothers when used early in the postnatal period (Fewtrell et al. 2006).

Expressed donor milk

Expressed DBM can be fore milk or hind milk, obtained either before or after the donor's own infant has fed from the breast; these two types of milk will have, respectively, lower or higher fat and energy contents than milk received by the breastfed infant. Mature donor milk will have a lower protein, sodium, zinc and copper content than that of milk produced in early lactation. A Cochrane systematic review (Quigley et al. 2007) compared outcomes in preterm infants fed DBM or formula and identified only eight studies, five of them RCTs. Meta-analysis of data from five trials suggested that infants fed DBM had a significantly reduced risk of developing NEC (typical relative risk 2.5), although feeding DBM was also associated with slower neonatal growth. Most of the studies considered were 20–30 years old and from an era when DBM was fed without fortification or mineral supplements, often as the sole diet. It is not clear whether similar effects would be seen when DBM is used in a more 'modern' context – as a supplement to MBM and supplemented with minerals and/or fortifiers. Only one trial (Schanler et al. 2005) compared nutrient-fortified DBM versus PTF as supplement to MBM. The study was unable to establish any short-term benefit for DBM over PTF. More recently, a human milk-based fortifier and PTF have become available and use of these products was associated with lower rates of NEC in a randomised trial when compared with bovine fortifiers and formulas (Sullivan et al. 2010).

Drip breast milk

This is the milk that drips spontaneously from the contralateral breast during feeding in a proportion of lactating mothers – about 20% produce significant quantities. Although previously used to feed preterm infants, including in older clinical studies, drip breast milk has a similar composition to fore milk, with very low fat and energy content (often around 50 kcal/100 ml in pooled milk); this method of collecting DBM is now not recommended and donor mothers are advised to express milk by hand or using a mechanical breast pump.

Fortified human milk

One solution to overcome the nutrient deficits in human milk for the preterm infant is to add a fortifier containing protein, energy, macrominerals, trace minerals and a comprehensive range of vitamins. Several are now commercially available (Table 16.9), usually in the form of a powder which is added to a fixed volume of milk. However, the addition of nutrients to a complex biological medium such as milk poses theoretical problems. In particular, breast milk varies greatly in composition, and the addition of a fixed supplement may result in some infants exceeding the upper recommended limit for certain nutrients while others remain below desirable intake levels. Fortification may also influence nutrient availability or alter the biological properties of human milk.

A review for the Cochrane collaboration, last updated in 2003, concluded that the use of multinutrient fortifiers is associated with short-term improvements in weight gain, linear growth, head growth, nitrogen retention and blood urea levels but that there is currently no evidence of long-term benefit, and insufficient evidence to be reassured that there are no deleterious effects (Kuschel and Harding 2004). It remains to be established whether overall outcome in infants fed fortified breast milk is better than that in infants fed a PTF when both diets provide similar nutrient intakes.

A small RCT (Arslanoglu et al. 2006) showed that adjustable fortification of human milk (based on the infant's blood urea concentration) resulted in greater weight and head circumference gains, which were significantly correlated with protein intake, than standard fortification. More recently, a 'humanised' milk fortifier, produced from pooled DBM processed to ensure the highest safety standards, has been developed. Clinical trials of the new fortifier, which avoids any exposure to cow's milk, have shown a significantly reduced risk of NEC, although this product is not yet commercially available (Sullivan et al. 2010).

Human milk banking

The National Institute for Health and Clinical Excellence (2010) has recently issued guidance on DBM banks and further advice can be obtained from the UK Association for Milk Banking (see Weblink). It is important to appreciate that, once milk has been collected, bacterially decontaminated, stored, frozen and thawed, pasteurised, exposed to light, aliquoted and instilled into feeding apparatus, it may have undergone qualitative alterations that render it significantly different from milk obtained by an infant during normal suckling.

Screening of breast milk donors for human immunodeficiency virus (HIV 1 and 2), human T-lymphotropic virus (HTLV type I and II), hepatitis B and C virus, and syphilis is advised (National Institute for Health and Clinical Excellence 2010). The risk of acquiring HIV from DBM is unknown, but there have been no reported cases of preterm infants infected in this way. Published evidence suggests that pasteurisation destroys HIV (Eglin and Wilkinson 1987). More recent studies reported that 'flash-heat' treatment of breast milk (similar to high-temperature, short-time pasteurisation) can be used to inactivate HIV-1 in resource-poor settings (Volk et al. 2010).

There are some concerns about cytomegalovirus (CMV) seroconversion in preterm infants receiving breast milk from seropositive mothers. However, the relative incidence of human milk-associated CMV infection and the severity of disease in premature infants are very low with no developmental abnormality at 24-month follow-up (Miron et al. 2005). Differences in CMV acquisition from fresh or frozen milk have been suggested and short-term high-temperature pasteurisation techniques were found to prevent CMV transmission more effectively than freezing (Schanler 2005). Different strategies to inactivate CMV and preserve non-nutritive benefits of breast milk are under investigation (Goelz et al. 2009).

'Term' infant formulas

For many years, formulas designed for full-term infants were used to feed LBW infants. Such formulas (Table 16.7) contain around 1.5 of protein/100 ml and 65–70 kcal/100 ml. Fed at 180–200 ml/kg, they provide only 2.7–3.0 g protein/kg/24 h – below the limit recommended for preterm infants (Table 16.2). Sodium, calcium and phosphorus intakes, together with those of several trace nutrients, do not meet the calculated needs of LBW infants. Data from a large

multicentre trial show that infants fed standard formulas grow more slowly in the short term than those fed PTF, and have substantially lower motor and mental development scores at 18 months and lower IQs at 7.5–8 years (Lucas et al. 1990c, 1998). In our view, standard formulas have no place in the future management of preterm infants under 2 kg body weight, and PTF should be used in their place. Soya formula should not be used for feeding LBW infants.

Special preterm infant formulas

In recent years, a variety of formulas have been designed to meet the theoretical nutrient needs of LBW infants (see Chapter 16 part 1). These formulas (Table 16.10) vary significantly in their detailed composition, and continue to evolve. Clinical trials have shown

that such formulas may carry a number of short-term advantages over unsupplemented human milk: they promote faster weight, length and head circumference gain (see below), reduce hospital stay and reduce the incidence of hyponatraemia, bone disease of prematurity, hypophosphataemia, hyperbilirubinaemia and some vitamin deficiencies. More importantly, at follow-up, infants previously fed PTF have an advantage over those fed standard term formula in linear growth, developmental scores and IQ (Lucas et al. 1998).

Diets for preterm infants: overview

In summary, the available evidence suggests that human milk has an important place in neonatal intensive care. Many infants tolerate human milk better than formula, and enteral feeds can be

established faster, reducing the requirement for parenteral nutrition (with its known hazards: see Ch. 17). The use of breast milk is likely to be associated with a reduction in the incidence of NEC and systemic infection, and is associated with improved cognitive outcome, lower blood pressure, more favourable plasma lipid profile and higher bone mass during childhood and adolescence. In addition, the slower initial growth rates seen in infants receiving human milk may be beneficial for later insulin resistance and arterial distensibility. However, in the preterm population, the risks and benefits of promoting growth must be balanced; poor early growth may have adverse consequences for short-term survival and for later cognitive development (Ehrenkranz et al. 2006) and bone health, whereas promoting growth (particularly during very early postnatal life) may be bad for later cardiovascular risk. On balance, in this group of infants current data clearly support the promotion of growth, since the later cardiovascular outcome of infants who grow well is no worse than that of infants born at term.

Our recommendation is to use breast milk, preferably the mother's own, but donor milk if it is not available, to establish

enteral feeds (up to 150 ml/kg) in infants of 28 weeks' gestation or less and in infants who have had prolonged intravenous feeding (when the gut may be atrophic) or prolonged respiratory disease. When mothers do not provide breast milk, PTF should be used as a sole diet from birth in larger, well babies and after the establishment of human milk feeds in smaller or ill babies. If no breast milk is available, either maternal or banked, PTF should be cautiously introduced. Although term formula is sometimes used to establish enteral feeds in infants who appear not to tolerate PTF, there is no scientific evidence to support this. If term formula is used in this situation, it should be replaced by PTF as soon as possible. PTF may also be used as a supplement when mothers elect to provide their milk but do not have sufficient for the infant's requirements. Breast milk should be supplemented with phosphorus as a minimum to prevent metabolic bone disease. A multivitamin breast milk fortifier may be added if growth is unsatisfactory once the infant is tolerating full enteral feeds with breast milk. Human milk-based formulas and fortifiers may become more widely available in the future.

However, preterm infants are not a homogeneous population, and with the survival of ELBW babies any single diet is now unlikely to be optimal from birth to discharge. For instance, both the ESPGHAN Committee on Nutrition panel (Agostoni et al. 2010) and International Consensus Recommendations (Tsang et al. 2005) have recommended different protein intakes for infants weighing less than or more than 1 kg. Furthermore, certain groups of babies appear more vulnerable than others to the effects of suboptimal nutrition. Lucas et al. (1990c) showed that small-for-gestational-age (SGA) preterm babies and males particularly were disadvantaged in terms of developmental scores in infancy if they were fed on mature pasteurised milk or standard term formula rather than a nutrient-enriched PTF. Further work is required to explore how diets can be tailored to individual patients' needs.

Route of administration of feeds

Infants less than 34 weeks' gestation seldom have adequately developed reflexes to suck, so that feeding has to be intragastric, transpyloric or intravenous (Ch. 17). Short-term partial parenteral nutrition, accompanied by gradually increasing enteral feeding, often needs to be employed in immature infants.

Intragastric feeding

Nasogastric or orogastric gavage feeding is the most commonly practised method of enteral feeding for preterm infants. An important pitfall to remember when giving human milk by tube is that significant loss of energy may occur from the adherence of fat to the feeding vessels. This process may be accentuated by the change in physical characteristics of the fat induced by freezing for long periods. Fat loss during continuous milk infusion can be reduced by using eccentric nozzle syringes with the nozzle in an uppermost position and set at an angle so that the open end of the syringe is higher than its plunger end (Narayanan et al. 1984). In addition, when a syringe pump is used to infuse human milk continuously the syringe should be positioned below the baby, otherwise the fat rises up the connecting tube towards the syringe and may never be received by the baby. Feeds should never be syringed in using pressure on the plunger. For advice on checking tube position and complications of tube feeding, see Chapter 21.

Transpyloric feeding

Transpyloric feeding (into the duodenum or jejunum) has been widely used in the past. There is no convincing evidence that it improves feed tolerance and growth, or reduces aspiration. Moreover, from a systematic review of nine randomised trials, transpyloric feeding was associated with a greater incidence of gastrointestinal disturbance (RR 1.45, 95% CI 1.05–2.09). There was some evidence that feeding via the transpyloric route increased mortality (RR 2.46, 95% CI 1.36–4.46). However, the outcomes of the study that contributed most to this finding were likely to have been affected by selective allocation of the less mature and sicker infants to transpyloric feeding (McGuire and McEwan 2007).

Cup feeding

Cup feeding can be a short-term adjunct to other feed methods in babies who are establishing breastfeeding, but requires careful supervision because of the risk of aspiration and is associated with significant losses from spillage. See Chapter 21 for more information.

Feeding schedules

Large, well, preterm infants

It is neither possible nor desirable to adhere to rigid feeding policies for LBW infants: gastrointestinal tolerance of enteral feeding is variable and concomitant illness may impose additional constraints, and therefore feeding must be managed on an individual basis.

The following guidelines are suggested for infants who are well enough to start full enteral feeds from the start. Feeding, by nasogastric tube if necessary, should start early to prevent hypoglycaemia, at about 2 hours of age. A commonly employed schedule for increasing feed volumes is to give, on the first four successive days, 60, 90, 120 and 150 ml/kg/24 h, and, for babies who require greater feed volumes than this, to make further daily increments to 180 ml/kg/24 h by day 10, and 200 ml/kg/24 h by day 14. There are few data on the rate at which bolus feeds should be instilled down a tube: most units favour gravity feeding over 10–20 minutes, rather than continuous infusion via a syringe pump. A systematic review of seven trials comparing continuous versus intermittent bolus feeding, involving 511 infants weighing less than 1500 g found no differences in time to achieve full enteral feeds and also no significant difference in somatic growth and incidence of NEC between feeding methods (Premji and Chessell 2003).

Most babies weighing more than 1500 g will tolerate 3-hourly feeds; smaller babies will need to be fed every 1–2 hours. Initially, the nasogastric tube should be aspirated at least 4–6-hourly, just before a feed. If the volume of aspirate is small, it may be replaced without altering the feed schedule; if it is significantly more than this or is 'dirty' rather than milky, it is advisable to reduce the feed intake accordingly, especially in infants showing increased abdominal girth. In infants who develop increasing abdominal distension, constipation or loose stools, with or without blood in the stools, enteral feeds should be stopped temporarily and NEC (Ch. 29.3) considered. If feed volumes need to be reduced below the required total fluid for more than a few hours, an intravenous infusion must be considered.

Sick and very immature preterm infants

In babies who are sick or very immature it is both undesirable and often impossible to commence full enteral feeds after birth, and an intravenous infusion must be commenced. There are theoretical and clinical trial data to support the idea of using small, subnutritional quantities of enteral food in babies who will not tolerate full feeds (see Ch. 29.3). In extremely immature infants (<27 weeks), however, even minimal enteral feeds may not be tolerated initially. A recent Cochrane review (Bombell and McGuire 2008) comparing delayed versus early initiation of enteral feeds included data from three small trials with a total of 115 very-LBW (VLBW) infants. These trials provided no evidence that delayed (>96 hours' postnatal age) introduction of progressive enteral feeds affected the incidence of NEC, mortality or other neonatal morbidities. However, with the small number of participants, important beneficial or harmful effects cannot be excluded. The timing of introduction of enteral feeds in preterm infants with severe intrauterine growth retardation, particularly when accompanied by absent or reversed end-diastolic blood flow, remains particularly controversial. Such infants may be at greater risk of NEC if they are fed, but they may also benefit more from the effects of minimal enteral feeding, in terms of adapting to enteral feeds. At present the best approach is probably to attempt minimal enteral feeding as soon as possible with human milk, being prepared for the fact that some of these babies are very slow to establish full enteral feeds.

A systematic review (McGuire and Bombell 2008) assessing the effect of slow (up to 24 ml/kg/day) versus faster rates of advancement of enteral feed volumes found three RCTs with a total of 396 VLBW infants. The authors concluded that there was no evidence that slow advancement of enteral feed volumes reduced the risk of NEC or all-cause mortality. Moreover, increasing the volume of enteral feeds at slow rates resulted in several days' delay in regaining birthweight and establishing full enteral feeds. When enteral feeding is commenced in very immature or sick infants, it may be advisable to use either a continuous infusion pump suitable for administering volumes to the nearest 0.5 ml/h or less, or slowly infused hourly boluses. Subsequent increments in feed frequency are a matter for clinical judgement, together with careful monitoring of enteral tolerance.

Psychosocial aspects

Practical involvement of parents in infant feeding during the period when suckling is not possible has considerable psychological benefits. Parents (under supervision) should be encouraged to measure out and give nasogastric tube feeds. Mothers who wish ultimately to breastfeed may start to put their baby to the breast from an early stage, provided the baby is well. A systematic review (Pinelli and Symington 2005) of 21 studies, 15 of which were RCTs, looking at the effects of non-nutritive sucking (NNS) during the administration of tube feeds found a significant decrease in length of stay in preterm babies receiving an NNS intervention. The review did not reveal a consistent benefit of NNS with respect to other major clinical variables (weight gain, energy intake, heart rate, oxygen saturation, intestinal transit time, age at full oral feeds and behavioural state). The difficulties encountered by mothers trying to express their own breast milk for their preterm infants are discussed on Ch. 21.

Postdischarge nutrition (Fewtrell 2003)

Preterm babies frequently leave hospital severely growth-retarded and fulfilling the criteria for 'failure to thrive', yet until recently little attention has been paid to their subsequent nutrition. Although there may be a considerable degree of catch-up during childhood, particularly for weight, in our cohort of 926 preterm infants, the mean height standard deviation score (SDS) in early adult life was significantly less than the population mean (mean SDS -0.41 (SD 1.05)). The height deficit was even greater for infants weighing less than 1250 g at birth and SGA (-0.81 (SD 0.95)) (Fewtrell et al. 2009).

The small size of preterm infants at discharge is likely to be associated with deficits of a variety of nutrients, including calcium, phosphorus, iron, zinc and copper. A study of nutrient intakes in hospitalised preterm infants found cumulative energy and protein deficits of 406 kcal/kg and 14 g/kg at 1 week and 813 kcal/kg and 23 g/kg at 6 weeks of age in infants less than 31 weeks' gestation (Embleton et al. 2001). Such deficits would inevitably increase in infants fed term formula or unsupplemented breast milk after discharge.

Four main dietary options are available for use in preterm infants after hospital discharge:

1. human milk
2. term infant formula
3. preterm infant formula
4. nutrient-enriched postdischarge formula (PDF).

Formula feeding postdischarge

A study of formula-fed preterm infants after discharge from hospital demonstrated that, when fed ad libitum, these infants frequently consume volumes far in excess of those usually recommended by paediatricians: 16% took more than 350 ml/kg/24 h, 50% consumed more than 165 kcal/kg/24 h and 35% more than 4 g/kg/24 h protein (Lucas et al. 1992a). Cooke et al. (1998, 2001) studied 129 preterm infants randomised to receive PTF or term formula up to 6 months postterm. Boys (but not girls) fed PTF after discharge showed significantly greater weight and length gain and larger head circumference by 6 months postterm than those fed term formula throughout. At 18 months postterm, boys previously fed PTF were, on average, 1 kg heavier, 1 cm longer and had 1 cm greater head circumference than those fed term formula. Body composition measurements made using dual X-ray absorptiometry suggested that the additional weight gain was composed predominantly of lean tissue rather than fat. There were no significant differences in neurodevelopment measured using the Bayley scales of infant development at 18 months.

Although the use of PTF after hospital discharge is associated with growth benefits, particularly in boys, infants fed on demand may consume high volumes of PTF, and this could result in potentially toxic intakes of certain nutrients such as vitamin D. Such considerations, together with the desire to promote catch-up growth and replenishment of nutrient stores after discharge, led to the development of special postdischarge formulas. These formulas were designed such that all nutrient levels are within the range set for a standard term formula, although towards the upper end of this range for a number of nutrients (Table 16.11). Compared with a term formula, PDFs have higher protein content to promote catch-up growth, accompanied by a modest increase in energy to allow utilisation of the additional protein, additional calcium and phosphorus to permit adequate bone mineralisation and additional zinc, trace elements and vitamins to support the projected increase in growth rates.

A Cochrane review comparing outcomes in preterm infants randomised to term formula or postdischarge formula identified seven RCTs including 631 infants and concluded that there was no strong evidence for beneficial effects of postdischarge formula on growth or developmental outcome (Henderson et al. 2007). However, the review did not include a gender subgroup analysis; in two large RCTs of postdischarge versus term formula, beneficial effects on growth were seen predominantly in boys (Carver et al. 2001; Lucas et al. 2001), consistent with the beneficial effects of preterm infant formula after discharge reported in boys but not girls (Cooke et al. 1998, 2001).

Breastfeeding postdischarge

Breast milk is strongly promoted as the optimum diet for preterm infants in hospital in view of its proven benefits. However, it is not clear whether unsupplemented breast milk meets the nutritional requirements of preterm infants after discharge. Whilst the number of mothers providing breast milk for their infant for at least part of the hospital stay has increased, the proportion of mothers fully breastfeeding their infant after discharge is variable. A recent survey in Denmark reported an exclusive breastfeeding rate of 60% among 478 preterm infants of gestational age <32 weeks after hospital discharge (Zachariassen et al. 2010), but the figure was around 20% in an American study (Furman et al. 1998). However, a greater proportion of infants receive some breast milk, along with an infant formula, for at least the first few weeks after discharge.

LCP, long-chain polyunsaturated fatty acid; AA, arachidonic acid; DHA, docosahexaenoic acid.

A number of studies have reported slower growth rates and lower bone mass in human milk-fed infants, at least in the short term. Lucas et al. (2001) studied 65 preterm infants who were breastfed (but allowed up to 2 oz of formula daily) for at least 6 weeks after discharge. Although similar in size to formula-fed infants at discharge, by 6 weeks postterm breastfed infants were significantly lighter and shorter than formula-fed infants (on average 513 g lighter and 1.6 cm shorter than infants fed PDF). Deficits persisted up to 9 months postterm, by which time all the breastfed infants were receiving term formula and solids. Collectively, these data suggest that preterm infants who are breastfed after discharge grow more slowly and have lower bone mass than formula-fed infants.

Whether the differences persist or indeed have any consequences for later outcome is under investigation.

Introduction of solid foods

There are no published data to guide either the optimal timing of weaning or the nature of solid foods for preterm infants. A recent document compiled by a group of experts in the UK and endorsed by the Neonatal Nurses' Association, community nurses and the Paediatric Group of the British Dietetic Association (King et al., 2008) recommended that weaning should start when the infant is between 5 and 7 months old actual age from birth, but also

emphasises the importance of looking for signs of readiness in the individual infant; these included the infant showing interest in other people eating, putting things into his/her mouth, seeming less satisfied with milk alone and ready for something new, and the ability to be easily supported in a sitting position.

On a practical level, preterm infants are at risk of developing feeding difficulties that may have a significant impact on their post-discharge nutrition and growth. Infants who require prolonged respiratory support, have delayed introduction and establishment of oral feeds or who develop chronic lung disease are particularly vulnerable, and are more likely to have feeding problems, especially cough and vomit during feeds, throughout the first year of life (Hawdon et al. 2000). Early intervention in such infants, before oral feeding is introduced, may help minimise the potential for aversion to oral feeding and maximise the development of oromotor skills.

The term growth-retarded infant

Growth-retarded term infants are known to be at risk of continued growth failure as well as learning and behavioural problems. However, until recently, relatively little attention has been paid to the nutritional management of such infants.

de Rooy and Hawdon (2002) studied metabolic adaptation in 65 SGA infants with birthweights below the second centile over the first week of life, in relation to their mode of feeding. Exclusively breastfed infants showed a significantly greater production of ketone bodies, with no increase in the incidence of hypoglycaemia,

suggesting better metabolic adaptation. Ketone body production was lowest in formula-fed infants and intermediate in partially breastfed infants. These data strongly support breastfeeding in healthy term SGA infants, although adequate maternal support is clearly required to achieve this.

Most data suggest that catch-up growth in SGA infants, if it occurs, is largely completed during the first 9 months of life. It is not clear at present why a minority of growth-retarded infants fail to catch up, and to what extent this reflects their genetic potential.

Findings from a randomised trial (Singhal et al. 2007) and several observational studies suggest that early growth acceleration (generally defined as upward centile crossing for weight) may have adverse consequences, increasing the risk of later obesity, insulin resistance and higher blood pressure. Thus, the short-term benefits of promoting catch-up growth in SGA infants (Fewtrell et al. 2001b) must be weighed against potential adverse consequences for later health. The balance of risks and benefits of promoting early growth is likely to vary depending on the environment (for example, developing versus developed world settings). For healthy term SGA infants in a developed country setting with low risk of infectious morbidity or mortality, current consensus is that it is not advisable actively to promote rapid catch-up growth. Available data suggest that breastfeeding should be encouraged as the optimal source of nutrition for these infants, since on average it produces more gradual catch-up growth, with better developmental outcome (Morley et al. 2004).

Transition to enteral nutrition	326
Conclusion	326

The fetus is nourished parenterally during pregnancy via the placenta. This is abruptly discontinued at birth and the vast majority of babies then make a successful transition to enteral feeding. Parenteral nutrition (PN) is indicated in the infant for whom feeding via the enteral route is impossible, inadequate or hazardous, because of malformation, disease or immaturity. Babies with congenital anomalies of the gut require PN until normal gut function has returned. In babies with necrotising enterocolitis or a chylothorax, resting the gastrointestinal (GI) tract for a prolonged period may be curative, and some babies with short gut require total or partial parenteral feeding for many months to allow gut adaptation. PN is essential for extremely preterm babies prior to enteral feeding or to supplement milk feeds, which can then be increased slowly while continuing to satisfy nutritional requirements.

The long-term impact of inadequate nutrition during the neonatal period is now becoming clearer. The third trimester is a critical period for neuronal development. Work in the rodent model has demonstrated permanent impairment in dendritic arborisation and axonal myelination if early nutrition is inadequate (Escobar and Salas 1995). Clinical trials of enteral nutrition in preterm human infants have suggested that nutrition during the same period may have an impact on long-term neurodevelopmental outcome (Lucas et al. 1998). Postnatal growth failure in preterm infants is associated with an increased incidence of cerebral palsy, developmental delay and abnormal neurology (Ehrenkranz et al. 2006). It is common in our neonatal units despite widespread use of PN (Cooke et al. 2004). A significant proportion of this postnatal growth failure occurs in the first few weeks of life, with subsequent inability to meet the demands of catch-up growth on top of the requirements for normal growth (Embleton et al. 2001). A recent observation study was carried out on a random sample of all hospital patients in the UK who were given PN. Neonatal cases from a total of 74 hospitals providing all levels of neonatal care were reviewed. This revealed wide variation in practice with significant delays in starting PN and inadequate nutritional content in approximately 40% of cases reviewed (National Confidential Enquiry into Patient Outcome and Death 2010). As PN is an expensive and potentially hazardous intervention (Table 17.1), it is important that it is prescribed carefully and effectively.

Composition of infusates

Fluids (see Ch. 18)

Preterm infants adapt poorly to inadequate or excessive fluid intake compared with term infants. They have increased amounts of extracellular fluid, their kidneys have poor concentrating and diluting ability (Ch. 18), they have a large surface area in relation to weight and their insensible water loss through the skin, especially in the first week, is high (Ch. 15).

Energy

The estimation of energy requirement takes into account the components of total heat production (basal metabolic rate, physical activity, specific dynamic action of food, thermoregulatory heat

Table 17.1 Risks associated with total parenteral nutrition

Metabolic
Hyperglycaemia Hyperchloraemic acidosis Metabolic bone disease of prematurity Abnormal aminogram Hyperlipidaemia
Line-related
Infection
Atrial or superior venocaval thrombus Pleural effusions Pericardial tamponade, peritoneal extravasation Tissue necrosis from extravasation injury
General
Cholestasis Gut mucosal atrophy

production) and the energy cost of growth. In preterm infants, the basal metabolic rate is about 40 kcal/kg/day (Reichman et al. 1982). The energy cost of activity is 4 kcal/kg/day with minimal handling (Reichman et al. 1982) and the specific dynamic action of PN is 13% of the basal heat production or 10% of the calories infused (Rubecz and Mestyan 1973). If a baby is nursed in a thermoneutral environment, an input of 50 kcal/kg/day is generally sufficient to match ongoing expenditure but it does not meet additional requirements of growth (see Ch. 16) (Heimler et al. 1993).

Growth failure will result unless additional energy is provided. The energy cost of gaining 1 g of new tissue is 5 kcal (Reichman et al. 1982). To achieve the equivalent of third-trimester intrauterine weight gain of 14–15 g/kg/day, an additional 70 kcal/kg/day is required. Parenterally fed infants, compared with those enterally fed, begin to grow at a lower energy intake because of smaller faecal energy losses and reduced energy expenditure. Nevertheless, the goal energy intake for a rapidly growing preterm infant is about 120 kcal/kg/day (see Ch. 16 part 1), or even higher in long-term ventilated infants with chronic lung disease, whose energy requirements are increased by 25–30% (Wahlig and Georgieff 1995).

Protein

The goal of supplying protein to the neonate is to achieve nitrogen retention at in utero rates without causing metabolic disturbance. Preterm infants will lose approximately 1% of their total protein stores each day if they are given glucose alone (Rivera et al. 1993). Amino acids therefore need to be started in the first 24 hours of life. A minimum of 1.5 g/kg/day is recommended in order to prevent catabolism, although this is insufficient to support growth (Rivera et al. 1993; Thureen and Hay 2001). Commonly the amino acid intake is then increased slowly over the next few days because of concerns about the ability of the preterm infant to metabolise protein. However a number of investigators have examined higher early amino acid infusion rates, ranging from 2.4 to 3.5 g/kg/day (Thureen et al. 2003; Ibrahim et al. 2004; Te Braake et al. 2005). All reported improved nitrogen retention without any adverse

effects in the short term. It may be that starting amino acids at full rates, or at least increasing rapidly, will go some way to minimising the time to regain birthweight.

Optimal parenteral protein requirements for growth, as determined by a variety of methods, are in the range 3.5–4.0 g/kg/day for extremely low birthweight infants and 3.2–3.8 g/kg/day for very low birthweight infants (Tsang 2005). The amount of amino acids required to achieve adequate catch-up growth, if there has been a period of poor early weight gain, is likely to be higher than this (Thureen and Heird 2005). The recommended requirements for term infants are somewhat lower at 2.0–3.0 g/kg/day (Koletzko et al. 2005).

Preterm infants require not only more amino acids than term infants but also qualitatively different amino acids. Cysteine, taurine, tyrosine and histidine have been considered as semiessential amino acids in preterm infants (Laidlaw and Kopple 1987). Conversion of methionine to cysteine and taurine, and of phenylalanine to tyrosine, is affected by enzyme immaturity. However, the addition of cysteine (Malloy et al. 1984) and taurine (Thornton and Griffin 1991) to PN solutions in preterm infants did not improve nitrogen retention or weight gain. Taurine is important in the conjugation of bile acids, although humans can also conjugate bile acids with glycine. Some investigators consider that the addition of taurine to total PN (TPN) reduces the incidence of cholestasis (Heird et al. 1987). Comparison of amino acid solutions based on the composition of egg protein and breast milk has shown that the latter results in a lower risk of high plasma phenylalanine levels but a higher risk of low tyrosine levels (Puntis et al. 1989; Mitton et al. 1993). No adverse neurodevelopmental outcome has been observed after hyperphenylalaninaemia induced by PN (Lucas et al. 1993). If adequate non-protein energy is provided, the risk of hyperphenylalaninaemia is reduced (intravenous energy intake of >34 kcal/g protein). Amino acid solutions designed for paediatric patients have been shown to result in a more favourable plasma aminogram, higher nitrogen retention and better weight gain in preterm infants (Helms et al. 1987; Mitton et al. 1993). Current amino acid preparations available for neonates are based on the plasma aminograms of either cord blood or breastfed term infants.

In order to utilise the amino acids efficiently, sufficient non-nitrogen energy must be provided. Energy intake should be at least 40–50 kcal/kg/day for optimal amino acid utilisation, because, with lower energy intakes, more of the infused amino acids are oxidised to meet endogenous energy needs and less remain for tissue synthesis. Zlotkin et al. (1981) found that, when energy intakes of more than 70 kcal/kg/day were given to preterm infants, the major determinant of nitrogen retention was the protein intake. Whether this non-protein energy is derived from glucose or fat makes no difference to the nitrogen-sparing effect.

Ammonia, plasma amino acid profiles and urea levels have all been used to monitor the tolerance and adequacy of amino acid intake in the clinical setting. Current neonatal preparations are well tolerated and thus monitoring ammonia and amino acid levels is no longer required routinely. Urea levels are monitored regularly and some clinicians will limit amino acid intakes in the presence of rising urea. However urea levels reflect hydration status, renal function and illness severity and have been shown not to correlate with protein intake (Ridout et al. 2005). In contrast a low urea may reflect inadequate intake.

Carbohydrate

The goal of carbohydrate provision for the neonate is to maintain euglycaemia and promote optimal growth and body composition.

The consensus interpretation of the neurophysiological and neurodevelopmental outcome data is currently that neonatal blood glucose concentration should be maintained above 2.6 mmol/l (Ch. 34.1). The risks of hyperglycaemia and glycosuria increase with decreasing gestation and birthweight (Louik et al. 1985).

The rate of endogenous glucose metabolism in well, fasting neonates has been estimated to be 4–6 mg/kg/min (Denne 1998). Some premature infants will require more than this to maintain a satisfactory blood glucose. Glucose infusions should be commenced at 4 mg/kg/min (10% dextrose at 60 ml/kg/day will provide an infusion rate of 4 mg/kg/min) and increased as required. If a concentration of more than 12.5% dextrose is required, this should be given centrally owing to the risks of subcutaneous tissue infiltration. Since glucose tolerance improves with increasing postnatal age the glucose infusion rate can usually be progressively increased. Excessive carbohydrate will theoretically increase CO₂ production, although it is uncertain whether this is ever of clinical relevance. It may also impair liver function by inducing the storage of triglycerides and other fatty acids within the liver cells. The European Society of Paediatric Gastroenterology, Hepatology and Nutrition recommends that preterm infants' maximum glucose intake should be 8.3 mg/kg/min while term infants may tolerate up to 13 mg/kg/min (18 g/kg/day) (Koletzko et al. 2005).

If hyperglycaemia occurs, the baby should be carefully assessed. Hyperglycaemia occurring in a previously metabolically stable baby may be the first sign of infection, although immature infants may have limited tolerance of intravenous glucose even when infused at physiological rates. Hyperglycaemia during glucose infusion appears to be due primarily to persistent endogenous hepatic glucose production secondary to an insensitivity of hepatocytes to insulin (Cowett et al. 1988). Insulin can be infused in infants who remain hyperglycaemic at a glucose infusion rate of 8 g/kg/day (6 mg/kg/min) (Ostertag et al. 1986), commencing at 0.05 units/kg/h. A randomised controlled trial in infants of below 1000 g birthweight with glucose intolerance has shown that insulin therapy improves glucose intake and weight gain (Collins et al. 1991). However the practice of prescribing early insulin replacement therapy in order to increase the glucose intake in very low birthweight infants appears to offer little clinical benefit and may be associated with increased risk (Beardsall et al. 2008) and is not currently recommended (Sinclair et al. 2009).

Lipid

The goals of providing fat to neonates are to prevent fatty acid deficiency, facilitate provision of lipid soluble vitamins and promote optimal growth and body composition.

Nitrogen sparing effects of carbohydrate and fat are similar in parenterally fed infants, although lipid has the benefit of being calorie-dense (Pineault et al. 1988; Van Aerde et al. 1994). Abnormal plasma fatty acid patterns have been noted within 2–3 days of lipid free alimentation, with a deficiency state in 10 days (Lee et al. 1993). Essential fatty acid deficiency can be prevented by as little as 0.5 g/kg/day of Intralipid (Lee et al. 1993), a fat emulsion derived from soybean oil containing 54% linoleic acid and 8% linolenic acid. While soybean-based emulsions have been the gold standard for many years, the balance of ω -3 and ω -6 fatty acids is probably not ideal for the preterm infant. Linoleic acid (an ω -6 polyunsaturated fatty acid (PUFA)) is the dominant fatty acid in soy-based emulsions. However there is concern that this has the potential to inhibit the production of ω -3 PUFAs, such as docosahexaenoic acid (needed for retinal and brain development). As the metabolites of the ω -3 and ω -6 fatty acids are anti-inflammatory and proinflammatory respectively, an imbalance may have an impact on the

infant's immune response. Olive oil-based emulsions contain oleic acid (ω -9 long-chain monounsaturated) as the main fatty acid and therefore may provide a more appropriate balance between ω -6 and ω -3 fatty acids. However studies have not shown any clinically significant effect to date (Webb et al. 2008). Fat emulsions containing equal proportions of long- and medium-chain triglycerides (LCT/MCT) have been used in infants, and one study showed greater nitrogen retention with LCT/MCT than with LCT emulsions (Unger et al. 1986).

Phytosterols found in soybean oils are thought to contribute to PN-associated liver disease. This, in addition to the proinflammatory effects of linoleic acid, has led to discontinuation of soy lipid emulsion as the mainstay of treatment. Fish oil has a high concentration of eicosapentaenoic acid, docosahexaenoic acid and ω -3 fatty acids. Recent experience has suggested that fish oil monotherapy has a potentially beneficial effect in infants with PN-related liver disease (Gura et al. 2008). The development of lipid emulsions combining soy, olive and fish oils and MCTs offers a potentially beneficial product which is currently being evaluated in the preterm population.

Lipid utilisation is limited and often unpredictable in preterm and in small-for-gestational-age infants, owing to deficient cellular uptake and utilisation of free fatty acids rather than low lipoprotein lipase activity (Rovamo et al. 1988). Carnitine plays an important role in the oxidation of fatty acids by facilitating their transport across mitochondrial membranes. Preterm infants fed parenterally with carnitine-free solutions develop low blood and tissue carnitine concentrations because of their small carnitine depots and limited capacity for carnitine biosynthesis. Carnitine supplementation, however, does not improve growth or lipid tolerance and is not recommended (Cairns and Stalker 2000).

There have been a number of concerns over the early use of lipid; however, randomised controlled trials have established the benefits and safety of parenteral fat commenced on the day of birth (Gilbertson et al. 1991; Sosenko et al. 1993; Ibrahim et al. 2004). Concern had been expressed about the effects of lipid infusion on respiratory function. However oxygenation and pulmonary haemodynamics in infants with severe respiratory distress syndrome were not affected when parenteral fat was infused at a dose of 1–4 g/kg/day (Brans et al. 1986; Gilbertson et al. 1991) but deteriorated when the infusion rate exceeded an equivalent of 6–7 g/kg/day (Pereira et al. 1980). An association between parenteral fat administration and coagulase-negative staphylococcal bacteraemia in infants has been found (Freeman et al. 1990) but there is no evidence that it impairs immune function in infants (English et al. 1981; Strunk et al. 1985). An increase in circulating free fatty acid levels can theoretically compete with bilirubin for binding to albumin. However, fat emulsion is also capable of binding unconjugated bilirubin (Thaler and Wennberg 1977) and infusions of 2–4 g/kg/day have been found to have no effect on total or unbound serum bilirubin (Brans et al. 1987). At levels of free fatty acids, bilirubin and albumin usually occurring in this population, significant displacement does not occur (Adamkin et al. 1992).

Free radicals generated when soy lipid emulsion undergoes peroxidation could be potentially damaging. Light-induced formation of triglyceride hydroperoxides can be prevented by covering the lipid emulsion with aluminium foil, although this has largely fallen out of fashion (Neuzil et al. 1995). There is also evidence suggesting that failure to photoprotect PN contributes to high blood glucose and triglyceride levels (Khasu et al. 2009). Lipid tolerance can be improved by using a continual infusion over 24 hours and by using a 20% rather than 10% concentration. Compared with 10% Intralipid, 20% Intralipid has a lower phospholipid/triglyceride ratio and liposomal content, and thus results in lower plasma

triglyceride, cholesterol and phospholipid concentrations (Haumont *et al.* 1989).

A 20% lipid emulsion should be started at 1 g/kg/24 h and increased daily by 1 g/kg to 3 g/kg/24 h as tolerated (Hilliard *et al.* 1983). Plasma triglyceride levels should be monitored (see Table 17.4, below), as plasma turbidity assessed by visual inspection or nephelometry does not reliably predict serum concentration (Schreiner *et al.* 1979). If the baby has poor growth but is tolerating lipids, the total dose can be increased to 3.5 g/kg/day. When triglyceride levels exceed 2.0 mmol/l, it is necessary to reduce or interrupt fat infusion until normal values are regained. The lipid infusion should be reduced or interrupted for 24–48 hours during acute sepsis, because of the reduced fat oxidation rate (Park *et al.* 1986).

Minerals

Early hyponatraemia in preterm infants is caused mainly by their high insensible water loss (Ch. 18, Ch. 15), while early hyponatraemia is caused mainly by water overload. Late hyponatraemia in preterm infants is due to limited tubular sodium reabsorption, and diuretic therapy may contribute (Al-Dahhan *et al.* 1983). No sodium should be added to intravenous fluids or PN until postnatal natriuresis has occurred (Ch. 18). Thereafter, 3–5 mmol/kg/day is recommended, to prevent late hyponatraemia, and further increased if the infant is receiving furosemide for chronic lung disease or has significant ongoing renal losses. Although a potassium intake of 1–2 mmol/kg/day is required for the growing preterm infant, it should be withheld in the first 3 days after birth in those who are extremely preterm, because they are at risk of developing non-oliguric hyperkalaemia from immature distal tubular function. Hypochloraemic alkalosis is prevented by a chloride intake of 2 mmol/kg/day. Chloride intakes in excess of 6 mmol/kg/day are inadvisable because of the risk of hyperchloraemic metabolic acidosis (Groh-Wargo *et al.* 1988). Hyperchloraemic acidosis can be avoided by replacing part of the sodium chloride load with sodium acetate (Olunfunmi *et al.* 1997).

Parenteral administration of calcium at 1 mmol/kg/day from birth can reduce early neonatal hypocalcaemia in preterm infants (Salle *et al.* 1977). Requirements calculated to match intrauterine accretion rates in a rapidly growing preterm infant are, however, higher than those used to maintain short-term homeostasis. PN solutions should contain 1.3–1.5 mmol/100 ml of calcium and phosphorus (molar ratio of 1:1 or a ratio of 1.3:1 by weight) and 0.2–0.3 mmol/100 ml of magnesium. Factors that affect solubility of calcium and phosphorus are discussed below (see Techniques, below). High intakes of calcium and phosphorus should only be given through a central venous line.

Trace elements and vitamins

Table 17.2 summarises the recommendations on parenteral minerals and trace elements for preterm infants based on expert consensus published by Tsang (2005). Trace elements are added routinely to the aqueous component of PN. Zinc and selenium levels should be monitored after the first month of prolonged PN, particularly in infants with underlying GI pathology. Because selenium and chromium are excreted mainly through the kidneys, intake may need to be reduced when renal function is impaired. The aluminium content of PN infusates may be up to 1 µmol/dl as a result of aluminium contamination of the components used, such as calcium gluconate, which can contribute up to 80% of the total aluminium load. As it has been suggested that this will adversely affect neurodevelopment, aluminium contamination should be reduced as far as possible (Bishop *et al.* 1997).

Table 17.2 Recommendations for intravenous mineral, trace elements and vitamins in very low birthweight infants (amount per kilogram per day)

Sodium	3–5 mmol
Chloride	3–7 mmol
Potassium	2–3 mmol
Calcium	1.5–2.0 mmol
Phosphorus	1.5–1.9 mmol
Magnesium	0.2–0.3 mmol
Zinc	6.1 µmol
Copper	0.3 µmol
Selenium	19–57 nmol
Manganese	18.2 nmol
Iodine	7.9 nmol
Chromium	1–5.8 nmol
Molybdenum	2.6 nmol

Table 17.3 Vitamins

RECOMMENDATIONS		COMPOSITION of VITLIPID (per ml)
Vitamin A	700–1500 IU	230 units
Vitamin D	40–160 IU	40 units
Vitamin E	2.8–3.5 IU	0.7 units
Vitamin K	10 µg	20 µg

Paediatric multivitamin preparations are available (Moore *et al.* 1986). Water-soluble vitamins can be added to either the aqueous or the lipid component. Fat-soluble vitamins should be added to the lipid component. If they are added to the amino acid solution as part of a multivitamin preparation, about 80% of vitamin A and 30% of vitamins D and E is lost during administration owing to adherence to tubing and photodegradation, especially during phototherapy (Gilles *et al.* 1983; Smith *et al.* 1988). By adding the vitamin preparation into the fat emulsion instead of the amino acid–glucose mixture, vitamin losses can be reduced and the risk of deficiency minimised (Baekert *et al.* 1988; Dahl *et al.* 1994). A dose of 4 ml/kg Vitlipid (Fresenius Kabi) will give an adequate amount of vitamin A (Table 17.3). Fat-soluble vitamin levels should be monitored in all babies requiring more than 1 month's PN.

Techniques

All preparations should be carried out under strict aseptic conditions using a laminar flow hood and terminal filtration with a 0.22-µm filter prior to delivery to the ward. PN should never be made up at ward level, neither should additions be made to the bag.

The solubility of calcium and phosphorus depends on other components within the infusate and the order in which they are mixed. The higher amino acid concentrations recommended for use in preterm infants help to enhance their solubility by decreasing the pH of the solution. Phosphorus should be added before calcium to avoid the high concentrations of phosphorus causing immediate precipitation with calcium. Precipitation with phosphates is more likely with calcium chloride than with the gluconate salt. Glycerophosphates may allow greater delivery of calcium and phosphorus because they are stable in solution and have equivalent retention rates to standard salts (Hanning et al. 1991; Raupp et al. 1991).

Administration

An infusion pump is required to maintain a constant rate of delivering the PN solution. A 0.22-µm bacterial filter is commonly used. Distal to the filter, a second infusion pump delivers the fat emulsion close to the intravascular catheter. It is important to minimise mixing of the fat emulsion with calcium and heparin as this increases the risks of formation of calcium-phosphorus crystals and flocculation of the lipid due to the destabilising effect of divalent cations (Raupp et al. 1988).

Although PN can be given peripherally it is preferable to use a centrally placed line. Fine Silastic lines inserted percutaneously or umbilical venous lines are the preferred central venous catheters in neonates (Ch. 44). These should provide secure central access for the duration of PN for the majority of neonates. In infants with a requirement for long term PN, insertion of a surgically placed central line and the addition of heparin (1 unit/ml) to the infusate further reduce significantly the incidence of phlebitis and thrombosis of both peripheral (Alpan et al. 1984) and central (Bailey 1979) venous catheters. PN has been administered routinely through umbilical arterial catheters. This has been found to be comparable to central venous catheters in efficacy and safety (Kanarek et al. 1991).

The importance of careful monitoring of the baby receiving TPN cannot be overemphasised (Table 17.4). Frequent monitoring is necessary when the PN is being increased and adjusted or the baby is clinically unstable. As the baby's condition stabilises and electrolyte requirements are unchanged for several days the frequency of monitoring can be reduced.

Hazards

Infections and technical complications

Infants on PN have an increased risk of bacterial sepsis caused by *Staphylococcus epidermidis* or *S. aureus* (Beganovic et al. 1988) and fungal sepsis caused by *Candida* (Weese-Mayer et al. 1987). The prevalence of catheter-related sepsis in infants ranges from 8% to 45%, with staff training playing a key role in its prevention (Puntis et al. 1989, 1991). The risk of polymicrobial bacteraemia is increased by manipulations of the parenteral infusate at the bedside (Fleer et al. 1983; Jarvis et al. 1983). Precautions which should be taken to minimise the risk of sepsis are listed in Table 17.5.

Complications of central venous catheterisation are discussed in Chapter 44.

Metabolic complications

The risks of abnormal plasma aminograms, hyperammonaemia, hyperchloraemic metabolic acidosis, metabolic bone disease and trace element deficiencies are minimised with the careful choice of

Table 17.4 Monitoring during parenteral nutrition

- ☐ Daily body weight and weekly body length and head circumference
- ☐ Initially during grading-up of parenteral nutrients or during periods of metabolic instability:
 - Strict fluid balance
 - 6–12-hourly blood glucose
 - Daily plasma sodium, potassium, calcium, urea and acid-base
 - Twice-weekly triglycerides
- ☐ When on full parenteral nutrition and during metabolic steady state:
 - Strict fluid balance
 - 12–24-hourly blood glucose
 - Twice-weekly plasma sodium, potassium, calcium, urea and acid-base
- ☐ Plasma magnesium, phosphorus, alkaline phosphatase, albumin, transaminases, triglycerides and bilirubin (total and conjugated) weekly
- ☐ Plasma amino acids and ammonia not usually routinely monitored
- ☐ Trace elements and fat-soluble vitamins should be monitored monthly

Table 17.5 Precautions to minimise the risk of sepsis

- Preparation and manipulation of parenteral nutrition solutions should only take place in the pharmacy
- Avoid carrying out manipulations in the ward
- Central venous catheters must be placed under strict aseptic conditions
- Skin exit site for catheter placed in area which can be meticulously cleansed
- Proper care of the site and all the connectors and tubings is essential
- The total parenteral nutrition line should not be broken for the administration of drugs
- The requirement for a central line should be considered daily and the line removed at the first opportunity

amino acid solutions and appropriate additives to the infusate. Cholestatic jaundice occurs in 10–40% of infants on PN (Ch. 29.1); it is very uncommon in those who receive it for less than 2 weeks, but up to 80% of those who require TPN for more than 2 months develop cholestasis (Beale et al. 1979). Likely mechanisms include immaturity of the hepatobiliary system (Merritt 1986), prolonged fasting (Rager and Finegold 1975), impaired bile secretion and bile salt formation (Sondheimer et al. 1978), coexisting sepsis (Kubota et al. 1988) and underlying medical conditions associated with hypoxia or GI conditions requiring surgery (Bell et al. 1986). In the vast majority, cholestasis resolves when enteral feeding is initiated, but progression to biliary cirrhosis (Pereira et al. 1981) can occur. Discontinuing the TPN for 1–2 weeks may allow significant recovery, as may discontinuing the lipids alone. The use of a fish oil-containing lipid emulsion in this situation offers a potential therapeutic approach (Gura et al. 2008). Minimisation of sepsis, in particular line-related sepsis, and commencement of enteral nutrition at the first possible opportunity will reduce the likelihood of PN-associated liver disease.

In view of the potential metabolic complications, parenteral lipids should be used with caution initially in infants with

fulminating sepsis, prior to adequate clinical stabilisation with antibiotic therapy. Amino acids and electrolyte solutions should be monitored with great care in infants with severely impaired renal function. The total nitrogen intake may be limited, but should not be discontinued completely, as this will result in catabolism.

Transition to enteral nutrition

In spite of the adequacy of PN in meeting nutritional requirements for postnatal growth, enteral feeding itself is vital for adaptation to extrauterine nutrition through its trophic effects on the GI tract and its physiological effects on GI exocrine and endocrine secretion and motility (Lucas et al. 1983). Milk feeds result in surges of secretion, glucagon, gastrin and motilin, all of which have trophic effects and mediate GI secretion and motility. It has been shown in human infants that enteral feeding is necessary for normal gastric acid secretion (Hyman et al. 1983). Enteral feeding is associated with increases in blood gastrin and motilin levels (Shulman and Kanarek 1993) and intestinal motor activity (Berseeth and Nordyke 1993). Glucagon, in addition to its role in GI motility, stimulates bile flow (Aynsley-Green 1983). Infants on TPN with no enteral intake secrete extremely dilute bile, a finding which may explain some of the adverse hepatobiliary changes associated with TPN (Al-Rabeeah et al. 1986). Those who are parenterally fed also have significantly fewer immunoglobulin-containing intestinal plasma cells than those who are enterally fed (Knox 1986). The early introduction of

milk feeds prescribed even in subnutritional quantities is therefore beneficial for growth, development and maintenance of normal structure and function in the GI and hepatobiliary systems (Berseeth 1995). Once enteral feeds are being absorbed the PN should be reduced proportionally in the majority of infants. Once the infant has tolerated 100–120 ml/kg/day enterally consideration should be given to removing the central line and discontinuing PN, in order to minimise the infection risk. In a small number of neonates with evidence of malabsorption it may be necessary to provide concentrated PN in addition to substantial amounts of enteral feed. Paediatric dietetic involvement with these infants is essential.

Conclusion

Despite the many unanswered questions, PN remains an essential part of the care of many preterm and sick neonates. The optimal nutritional input for long-term health remains unknown. But it is becoming clear that many babies suffer extrauterine growth restriction in our neonatal intensive care units because of excessive caution with both PN and introduction of enteral feeds. Because of the potential complications PN should only be used in neonatal units where there are appropriate facilities and staff. Access to an appropriately skilled dietician and pharmacist is essential. PN is life-saving in many instances of neonatal GI failure, benefits long-term health and is an essential facet of modern neonatal intensive care.

Appendix: How to write a total parenteral nutrition (TPN) prescription

There are two approaches to the provision of neonatal TPN. The first is to use standard bags, that is, bags containing the desired quantity of amino acids, dextrose and electrolytes for a preterm infant receiving 150 ml/kg/day TPN. Therefore the nutrients are increased proportionately as the fluid volume is increased over the first week. These have the advantage of cost and convenience and are suitable for the majority of preterm infants. They also have the advantage of minimising prescriber error and can be useful in units with limited access to specialist paediatric dietetic and pharmacy services. Those infants with high electrolyte requirements, a significant volume of non-nutritional infusates or prolonged fluid restriction may benefit from individualised prescriptions. Some units use individualised prescriptions for all their patients for this reason; others have agreed a small number of standard bags with varying

concentrations of nutrients. Many units use a mixture of standard bags to enable PN to be commenced outside working hours, with individualised PN commencing the next working day.

The method of prescribing TPN also varies widely across units. The precise volume and concentrations of amino acid, dextrose and electrolyte solutions may be calculated in the neonatal intensive care unit or in the pharmacy, with or without the aid of a computer program. It is important for each hospital to assess its processes for all sources of potential human error and minimise this. In St Michael's Hospital, Bristol, we prescribe the desired quantity of nutrients for each individual baby and the calculations are carried out in the pharmacy. It is important to be familiar with the exact process in each hospital as 15% dextrose in one hospital may refer to an overall concentration of 15% while in another it may mean

that 15% dextrose has been added to the solution, resulting in a significantly more dilute product.

General guidelines

- Decide the total daily fluid intake for the baby.
- Subtract all other intravenous infusion volumes (such as arterial line fluid or inotropes).
- Order parenteral nutrition (PN) for the remaining volume. As the enteral input increases, the intravenous protein, lipid and carbohydrate intake will reduce proportionately.
- When calculating the desired sodium intake, remember to take into consideration any saline or sodium bicarbonate infusions.

Protein

- Start early (within the first 24 hours if possible for all preterm infants).
- Start at 1.5 g/kg/day.
- Use a neonatal formulation.
- Increase by 1 g/kg/day to a total of 3.5 g/kg/day.
- Use with caution in babies with renal impairment (may need restriction to 2.5 g/kg/day) or with suspected inborn errors of metabolism (stop while investigations are awaited).

Dextrose

- Prescribe as mg/kg/min, starting at 6 mg/kg/min.
- Increase by daily increments of 2 mg/kg/min if tolerated to a maximum of 8.3 mg/kg/min.
- If using a peripheral cannula, note that the maximum overall dextrose concentration of the solution should be 12.5%.

Lipid

- Start at 1 g/kg/day on day 1 of PN. Use 20% emulsion.
- Increase by 1 g/kg/day to a maximum of 3.5 g/kg/day.
- Check triglyceride levels after a 4-hour lipid-free period twice weekly.
- Use with caution in babies with acute sepsis (temporary lipid intolerance), labile pulmonary hypertension (altered prostaglandin synthesis) or severe jaundice (fatty acid displacement of bilirubin from albumin).

Electrolytes and minerals

- Add sodium when the plasma sodium starts to fall, and titrate. The usual maintenance dose is a total of 2–4 mmol/kg/day. Allow for sodium content of other infusions. Once sodium intake is greater than 3 mmol/kg/day, use sodium acetate.
- Start potassium at 1–2 mmol/kg/day on day 3 and titrate.
- Start calcium and phosphate at 1–1.5 mmol/kg/day on day 1. Discuss with pharmacist if higher concentrations are desired.
- Start magnesium at 0.2 mmol/kg/day and titrate.
- Add maintenance trace elements, such as Peditrace (Fresenius Kabi) 1 ml/kg/day.

Vitamins

- Add water-soluble vitamins to amino acid solution from day 1, such as Solvito N (Fresenius Kabi) 1 ml/kg/day.
- Add fat-soluble vitamins to lipid emulsions from day 1, such as Vitlipid N Infant (Fresenius Kabi) 4 ml/kg/day to a maximum of 10 ml.

Introduction

This chapter will discuss the principles of newborn electrolyte and water balance and present a practical approach to clinical management. Renal function, clinical monitoring and renal disease are discussed in [Chapter 35 part 1](#).

Postnatal alterations in body water distribution

The newborn baby's body is largely composed of water. The extracellular compartment forms around 65% of bodyweight at 26

weeks' gestation, reducing to 40% at term and 20% by the age of 10 years ([Fig. 18.1](#)) ([Friis-Hansen 1961, 1983](#)). Superimposed on this gradual reduction with age is a more abrupt contraction that occurs shortly after birth ([Shaffer et al. 1986; Bauer and Versmold 1989; Shaffer and Meade 1989; Bauer et al. 1991; Heimler et al. 1993; Singhi et al. 1995](#)). This is due to loss of the interstitial fluid component of the extracellular fluid (ECF) compartment and is closely related to cardiopulmonary adaptation. The contraction of ECF accounts, at least in part, for early postnatal weight loss and occurs rapidly in healthy babies, but is delayed in babies with respiratory distress syndrome (RDS) ([Modi and Hutton 1990](#)).

Several studies suggest that the contraction of the ECF is triggered by atrial natriuretic peptide released in response to increased atrial stretch as pulmonary vascular pressure falls ([Kojima et al. 1987; Tulassay et al. 1987; Rozycki and Baumgart 1991; Bétrémieux et al. 1995](#)) and left atrial venous return increases. The intravascular compartment may also be acutely expanded during birth by the reabsorption of lung liquid and the effect of a variable placental transfusion. As the timing of the diuresis/natriuresis is to some extent related to the fall in pulmonary vascular pressure, it is not surprising that attempts to improve the course of RDS with diuretics have not shown benefit ([Brion and Soll 2001](#)).

A corollary of the isotonic loss of ECF is that net water and sodium balance in the first days after birth is negative ([Fig. 18.2](#)) ([Shaffer and Weismann 1992](#)). This is borne out by the observation that in newborn babies an increase in sodium intake leads to an increase in excretion ([Rees et al. 1984b; Shaffer and Meade 1989; Lambert et al. 1990](#)) until contraction of the extracellular compartment occurs. Sodium balance then becomes positive, commensurate with growth. However, preterm babies have a limited capacity to excrete a sodium load (see [Ch. 35 part 1](#)), so that, despite increasing excretion in response to an increase in intake, sodium retention readily occurs ([Costarino et al. 1992; Bétrémieux et al. 1995](#)). If there is concurrent restriction in the intake of water, these babies readily become hypernatraemic ([Shaffer and Meade 1989](#)). If a more liberal intake of water accompanies the intake of sodium, isotonic expansion of the extracellular compartment is the result, evidenced by weight gain at a time when weight loss is to be expected. In most babies, this cumulative positive balance is lost later, so that the normal postnatal change in body water distribution occurs but is delayed ([Bétrémieux et al. 1995](#)). Delayed loss of extracellular water increases the risks and severity of respiratory

illness in the newborn (Mohan et al. 1984; Rojas et al. 1984; Singhi and Chookang 1984; Singhi et al. 1985; Hartnoll et al. 2000b) and weight gain in the first days after birth, in babies with RDS, is associated with an increased risk of developing chronic lung disease (Van Marter et al. 1990).

Present-day management involving antenatal steroid therapy, postnatal surfactant, good intrapartum care and immediate postnatal stabilisation has modified the natural history of RDS so that cardiopulmonary adaptation generally occurs rapidly and the postnatal loss of ECF occurs imperceptibly, as in a full-term baby. In the pre-surfactant era, the abrupt onset of diuresis/natriuresis (Modi and Hutton 1990) heralded the improvement in respiratory function.

Non-renal influences on water balance

Insensible water loss occurs through the skin, respiratory tract and in stool. Stool water loss is usually small and usually less than 5 ml/kg/24 h in the first days after birth. The upper respiratory tract warms and humidifies inspired gases, and full saturation (44 mg/l) is achieved by the mid-trachea. If the upper respiratory tract is bypassed with an endotracheal tube, respiratory water loss must be reduced by adequate humidification of inspired gases. Humidification is also advisable when delivering low-flow oxygen and during continuous positive airway pressure.

The skin is an important regulator of water balance in extremely preterm babies. Transepidermal water loss reflects skin immaturity and may be considerable, even exceeding urine volume. Sodium is not lost through the skin, because babies born below 36 weeks' gestation do not sweat, though this develops within the first 2 weeks after birth (Harpin and Rutter 1982).

The stratum corneum of the skin consists of overlapping dead epidermal cells filled with keratin that form a barrier to water loss. Keratinisation begins at around 18 weeks' gestation, but the fetal epidermis is still very thin at 26 weeks and the stratum corneum is barely visible. During the last trimester, the epidermis and stratum corneum thicken and keratinisation becomes more marked (Evans and Rutter 1986). Each millilitre of water that evaporates from the skin is accompanied by the loss of 560 calories of heat, and so it is difficult to keep a baby with a high transepidermal water loss warm. This is the principle underlying the practice of placing extremely preterm babies in a plastic bag at delivery for thermal protection (see Ch. 15).

Skin maturation, unlike the maturation of renal function, is accelerated by birth, but not by antenatal steroid therapy (Jain et al. 2000). Transepidermal loss falls exponentially with increasing gestational and postnatal age (Fig. 18.3) (Hammarlund and Sedin 1979; Hammarlund et al. 1982, 1983; Sedin et al. 1985). After 32 weeks' gestation, water loss through the skin is around 12 ml/kg/day (Rutter 1989). Transepidermal loss is influenced by ambient humidity, skin integrity, environmental and skin temperature, air speed and radiant heat sources, including phototherapy (Tables 18.1 and 18.2). Radiant heat sources can increase transepidermal water loss by a factor of up to 0.5–2 (Rutter 1989). A high environmental humidity reduces transepidermal water loss, an effect that is most marked in the most immature infants (Fig. 18.4) (Hammarlund and Sedin 1979). Insensible water loss can be reduced to less than 40 ml/kg/day in infants weighing less than 1000 g if ambient humidity is maintained above 90% (Takahashi et al. 1994). Humidification is easier with an incubator, particularly if double-walled, but a low-cost stratagem is to use bubblewrap or other plastic sheeting and a humidified body box to achieve a high

Fig. 18.3 Transepidermal water loss in relation to gestational age at birth at different postnatal ages in appropriate-for-gestational-age infants. (Adapted from Sedin *et al.* (1985).)

Fig. 18.4 The effect of ambient relative humidity on transepidermal water loss (based on the data of Hammarlund and Sedin 1979). (Reproduced from Rutter (1989).)

Table 18.1 Factors influencing insensible water loss

INCREASED LOSS	DECREASED LOSS	INCUBATOR
Lower gestational age	Clothing	Body box
Lower postnatal age	High humidity	Plastic blanket
Denuded/broken skin		Good skin care
Increased skin temperature		Topical ointments and emollients
Increased activity		Humidification of inspired gases
Increased environmental temperature		High humidity
Radiant heat sources		
Radiant warmers		
Phototherapy units		
Draughts		
Excessive crying		

Table 18.2 Transepidermal water loss at an ambient humidity of 50% (mean \pm sd)

GESTATIONAL AGE (weeks)	n	POSTNATAL AGE (days)					
		0–1	3	7	14	21	28
25–27	9	129 \pm 39	71 \pm 9	43 \pm 9	32 \pm 10	28 \pm 10	24 \pm 10
28–30	13	42 \pm 13	32 \pm 9	24 \pm 7	18 \pm 6	15 \pm 6	15 \pm 6
31–36	22	12 \pm 5	12 \pm 4	12 \pm 4	9 \pm 3	8 \pm 2	7 \pm 1
37–41	24	7 \pm 2	6 \pm 1	6 \pm 1	6 \pm 1	6 \pm 0	7 \pm 1

Reproduced from Hammarlund *et al.* (1983).

humidity microenvironment immediately around the baby. The degree of humidification that can be achieved without causing condensation ('rain-out') on the inner wall of the incubator is dependent on the temperature gradient across the incubator wall. Condensation predisposes to skin maceration and should be avoided. Draughts should be eliminated. Stripping of the stratum corneum and deeper abrasions of the skin can be reduced by using non-abrasive tape such as Micropore, neonatal electrodes and skin protectants, prior to affixing urine bags and electrodes. Water-impermeable barriers, such as soft paraffin, or topical ointments reduce transepidermal water loss (Pabst et al. 1999; Wananukul and Praisuwanna 2002) but concern about increased infection and difficulty in fixing electrodes have limited their use. Adequate provision of fluid is also necessary, using a system that allows the intravenous glucose delivery rate to be altered independently of fluid volume in order to avoid hyperglycaemia (Al Rubeyi et al. 1994), osmotic diuresis and worsening of the situation. The extent to which transepidermal water loss is reduced, hypernatraemic dehydration and hyperglycaemia avoided and temperature stability maintained is an index of the quality of nursing and medical care and a useful measure for audit.

Clinical implications of postnatal and developmental changes: constructing a fluid prescription

Didactic recommendations are unnecessary. With an understanding of the principles involved, a prescription tailored to the needs of the baby can be constructed. Fluid management in common situations in neonatal intensive care is summarised in Tables 18.3–18.5.

The first days after birth

The goal of fluid management during the period of postnatal adaptation is to permit an isotonic contraction of the extracellular compartment and a brief period of negative sodium and water balance.

Water should be provided in an intake sufficient to allow the excretion of a relatively small initial renal solute load (Ziegler and Fomon 1971) and, in very preterm babies, to maintain tonicity in the face of initially high, but rapidly falling, transepidermal losses.

Table 18.3 Estimated starting intravenous intake, at an ambient humidity of 50%*

GESTATIONAL AGE (weeks)	BIRTHWEIGHT (kg)	APPROXIMATE TRANSEPIDERMAL WATER LOSS (ml/kg/24 h)	ALLOWANCE FOR URINE OUTPUT (ml/kg/24 h)	ESTIMATED INTAKE RANGE (ml/kg/24 h)	SUGGESTED STARTING VOLUME (ml/kg/24 h) [†]
<27	<1.0	120	30–60	150–180	150 [‡]
27–30	1.0–1.5	40	30–60	70–100	90
31–36	1.5–2.5	15	30–60	45–75	60
>36	>2.5	10	30–60	40–70	60

*At higher ambient humidities, transepidermal water losses will be reduced and requirements will be lower.
[†]Once sustained weight loss of at least 5% is achieved, proceed to the intravenous volume necessary to support nutritional goals without stepwise increments.
[‡]A cautious approach, commencing at the lower end of the estimated requirement, is recommended.

Table 18.4 Goals of immediate fluid management in extremely preterm babies

GOAL	MEANS OF ACCOMPLISHING GOAL
Minimise insensible water loss	Provide high humidity around infant using incubator or body box and plastic sheeting; minimum handling; meticulous skin care; eliminate draughts
Facilitate loss of extracellular fluid	Minimise intravenous sodium administration until postnatal diuresis/natriuresis marked by weight loss is underway
Maintain glucose homeostasis	Use a variable glucose delivery system if glucose tolerance is unstable (Al Rubeyi et al. 1994)
Optimise nutritional support	Commence parenteral and minimal enteral nutrition on day 1; stepwise increments are unnecessary in stable infants
Maintain renal perfusion	Monitor blood pressure, core–peripheral temperature gap, capillary refill time, urine output, cardiac function and central venous pressure; use volume and inotropic support as necessary

Table 18.5 Common clinical problems in fluid balance management

PROBLEM	ACTION
Respiratory distress syndrome	Initial infusion volume determined by anticipated insensible water loss; delay maintenance intravenous sodium administration until postnatal diuresis/natriuresis marked by weight loss is underway
Patent ductus arteriosus	Routine fluid restriction inappropriate as this will compromise nutrition; fluid-restrict if there is evidence of heart failure; indometacin/ibuprofen toxicity is exacerbated by dehydration
Severe birth asphyxia at term	Anticipate possibility of renal failure; 0.9% NaCl may be necessary for initial resuscitation and restoration of renal perfusion; restrict maintenance intake to 20–30 ml/kg/day until renal function can be assessed; central vascular access likely to be necessary for infusion of hypertonic glucose
Chronic lung disease	Avoid prolonged periods of fluid restriction; poor nutrition will worsen prognosis; diuretic-induced chronic sodium depletion will further compromise growth
Necrotising enterocolitis	Intestinal fluid loss may be considerable; interpretation of changes in body weight is difficult; profound intravascular volume depletion may be present without weight loss; monitor toe–core temperature gap; provide isotonic volume replacement (0.9% NaCl) if temperature gap exceeds 3°C
Preoperative	Fluid intake should not be reduced preoperatively; the infant should be well hydrated
Intraoperative	Minimise transepidermal water loss; administer glucose 5% or 10% in 0.9% NaCl during surgery
Postoperative	Unrecognised hypovolaemia is common and may contribute to postoperative hyponatraemia; infuse glucose 5% or 10% in 0.9% NaCl for at least 12 hours following surgery

Estimate the likely magnitude of insensible water loss using the information presented in [Figures 18.3 and 18.4](#) and [Table 18.2](#). A rational initial intravenous fluid volume would be the sum of an allowance for urinary water of 30–60 ml/kg/day plus estimated insensible water loss ([Table 18.3](#)) ([Modi 1997](#)). Given present-day care and an ambient humidity in excess of 50%, this usually equates to around 100 ml/kg/day for babies below 1500 g. If insensible water losses are predicted to be high, for example during the period immediately after delivery when the baby is being stabilised, start with a high intake but reduce this once a high-humidity environment is established. As it is not possible to predict precisely transepidermal water loss, the integrity of renal function or the timing of the postnatal natriuresis/diuresis, the adequacy of the estimate must be assessed within 6–8 hours.

The immediate administration of maintenance sodium in parenteral fluid is unwarranted and adversely affects respiratory outcome even in infants exposed to antenatal steroids. [Costarino et al. \(1992\)](#) compared sodium restriction for 5 days after birth with immediate administration of 3–4 mmol/kg/day in a blind trial. Water was prescribed independently. In the latter group sodium balance was positive on the first day after birth and there was a significantly higher incidence of bronchopulmonary dysplasia (BPD). [Hartnoll et al. \(2000a\)](#), in a blind, controlled trial, randomised infants born at 25–30 weeks' gestation to receive a parenteral sodium intake of 4 mmol/kg/day from the first day after birth or when a weight loss of 6% had occurred. ECF volume was measured at birth and on day 14. A significant reduction in ECF volume was observed in the group who received the delayed sodium intake, in contrast to the early-intake group, in whom no reduction was seen. By the end of the first week, 35% of babies in the delayed-intake group and 8.7% of the early-intake group, and by 28 days after birth 40% of the delayed-intake group compared with 18% of the early-intake group, no longer required additional oxygen. There was no difference between the groups in the rate of reduction in pulmonary artery pressure ([Hartnoll et al. 2001](#)), suggesting that the poorer respiratory outcome in the early-intake group was not

attributable to delayed cardiopulmonary adaptation but rather to persistent expansion of the extracellular compartment and delayed clearance of pulmonary interstitial fluid.

Intravenous sodium in maintenance fluid should be avoided until the physiological postnatal diuresis/natriuresis ([Modi and Hutton 1990](#); [Bétrémieux et al. 1995](#)) is underway, marked clinically by the onset of weight loss ([Bauer et al. 1991](#); [Singhi et al. 1995](#); [Tang et al. 1997](#)). There is no 'correct' figure for postnatal weight loss, as hydration at birth is variable ([Tang et al. 1993](#)) and birthweight does not correlate closely with extracellular water volume ([Shaffer et al. 1986](#)). Early postnatal weight loss reflects both the loss of body water and the loss of body solids. With improved nutritional support for preterm babies, early postnatal weight loss is diminished, though body water loss remains the same. In a study comparing healthy preterm babies with a group with RDS, during the first week after birth, both groups lost an identical amount of body water, namely 10% of the total body water content at birth. However, the healthy babies lost a maximum of 5.9% of birthweight, in contrast to a loss of 8.6% in the RDS group. This was because the healthy babies received a higher energy intake and gained solids to a significantly greater extent ([Fig. 18.5](#)) ([Tang et al. 1997](#)).

Glucose delivery should commence at around 7 mg/kg/min. Increasingly this is delivered with amino acids as parenteral nutrition immediately after birth. When glucose requirements are unstable the use of 5% and 50% glucose solutions delivered through a Y connection allows the glucose delivery rate and the volume infused to be readily altered independently ([Barr et al. 1977](#)) ([Table 18.6](#)).

Fluid 'restriction'

Neonatal paediatricians have long been concerned about 'excessive' fluid intake. Associations have been described between 'high' fluid intakes and increased risk of symptomatic patent ductus arteriosus ([Stevenson 1977](#); [Bell et al. 1980](#)), necrotising enterocolitis ([Bell](#)

Fig. 18.5 Weight, total body water (TBW) and body solids during the first week after birth in healthy preterm babies (dotted line) and babies with respiratory distress syndrome (solid line). Values (mean \pm 95% confidence interval) are expressed as a percentage of the value at birth. (Adapted from Tang et al. (1997).)

et al. 1979) and BPD (Brown et al. 1978; Van Marter et al. 1990; Costarino et al. 1992). On the basis of a systematic review of four randomised trials (Bell et al. 1980; von Stockhausen and Struve 1980; Lorenz et al. 1982; Tammela and Koivisto 1992), only one of which found a significant reduction in the subsequent diagnosis of a patent ductus arteriosus and no overall difference in BPD, 'careful restriction' of fluid intake has been recommended (Bell and

Acarregui 2001). However the term 'fluid restriction' is imprecise, and covers a wide range of water and sodium intake. Sodium intake was not controlled in these studies, so that increased 'fluid' meant an increased intake of both sodium and water. It is primarily the increased intake of sodium and resulting expansion of the extracellular compartment that appears responsible for the increase in morbidity.

The growing infant

Once the phase of immediate postnatal adaptation is over, the management of fluid and electrolyte balance must be tailored to the paramount demands of growth. It is questionable whether step-wise increments in parenteral nutrition are necessary once postnatal weight loss has been achieved as stable preterm babies are capable of excreting large volumes of water (Coulthard and Hey 1985; Modi 1997) and tolerating the metabolic load of immediate total parenteral nutrition. Milk feeds should be commenced concurrently providing enteral feeding is indicated (Ch. 16, Ch. 29.3). The energy density of parenteral nutrition should determine the volume prescribed, with the target a nutritional intake in excess of 100 kcal/kg/day. Once fully enterally fed, preterm babies may require in excess of 200 ml/kg/day of breast milk to achieve satisfactory growth, though non-renal, not renal, factors may limit tolerance.

Sodium is essential for growth, and a deficiency inhibits DNA synthesis in the most immature cells (Ostlund et al. 1993). Chronic limitation of intake is associated not only with extracellular volume contraction and poor weight gain, but also with poor skeletal and tissue growth (Chance et al. 1977; Haycock and Aperia 1991; Wassner 1991; Haycock 1993) and adverse neurodevelopmental outcome (Haycock 1993). In babies below 32 weeks' gestation fed intravenously, commence sodium administration at 4 mmol/kg/day once 5% weight loss has been achieved. Human milk provides about 1 mmol/kg sodium daily in a volume of about 150 ml/kg (Ch. 16, Table 16.1, 15 mg/100 ml). If retained, this is sufficient for normal growth. The full-term baby has efficient renal tubular and intestinal reabsorption but extremely immature babies require around 4 mmol/kg/day, or more if, for example, they are on treatment with diuretics (Haycock and Aperia 1991). The earliest sign of chronic sodium depletion will be poor weight gain, and not hyponatraemia, which is a late occurrence. A sodium intake of around 4 mmol/kg/day should continue until at least 32 weeks' postmenstrual age, by which time maturation of sodium conservation is likely to have occurred (Roy et al. 1976; Al-Dahhan et al. 1984).

Monitoring fluid balance

Fluid balance should be monitored carefully and is the responsibility of both medical and nursing staff. All too often, a failure to detect a problem in its early stages leads to a potentially reversible situation becoming irreversible. If a baby is unwell and requiring intensive care, or is largely dependent on intravenous fluids, the serum sodium, potassium, creatinine and bodyweight should be measured daily, and urine output monitored continuously (Table 18.7). Nursing charts should be designed so that hourly intake and output volumes can be recorded if required. Accurate weighing is important, taking the weights of attachments into account and recording net weight. Isotonic expansion of the extracellular compartment will be missed if changes in bodyweight are not considered in conjunction with the serum sodium concentration. Satisfactory fluid management is marked by a urine flow rate of at least 0.5–1 ml/kg/h on the first day, rising to 2–3 ml/kg/h

Table 18.6 Example of variable glucose delivery utilising simultaneous 5% and 50% solutions delivered through a Y connection (Al Rubeyi et al. 1994)

GLUCOSE DELIVERY RATE (mg/kg/min)	5% GLUCOSE INFUSION RATE (ml/kg/h)	50% GLUCOSE INFUSION RATE (ml/kg/h)	TOTAL VOLUME (ml/kg/24 h)
7	2.3	0.6	70
	5.5	0.3	140
5	2.6	0.3	70
	5.8		140

Table 18.7 Monitoring fluid balance in acutely ill infants

VARIABLE	FREQUENCY	COMMENTS
Weight	Daily	Steady initial loss of 1–2% daily; maximum weight loss variable but usually in the range of 5–10%; weight gain should have commenced by 7–10 days
Urine output	Continuously	Review 4–8-hourly; should exceed 0.5 ml/kg/h on day 1 in extremely preterm infants; thereafter, 2–3 ml/kg/h in all infants; less than 1 ml/kg/h requires investigation
Serum sodium	Daily or twice daily	132–144 mmol/l
Serum potassium	Daily or twice daily	3.8–5.7 mmol/l; spurious elevation due to haemolysis common
Serum creatinine	Daily	Usually a steady decline after birth, although a rise is not unusual in very preterm babies (Miall et al 1999).

thereafter, daily weight loss of the order of 1–2%, followed by weight gain of the order of 14–16 g/kg/day once a balanced energy intake greater than 100 kcal/kg/day has been achieved, a steady fall in serum creatinine and Na and K concentrations within the normal range (Table 18.7). The interpretation of urinary indices, urine flow rate and serum creatinine are discussed in Chapter 35 part 1.

Common clinical problems

Hypernatraemia and hyponatraemia

Changes in the serum sodium concentration reflect both sodium and water balance. In hypernatraemia (serum sodium >145 mmol/l) there is an absolute or relative deficit of water in relation to body sodium. In hyponatraemia (serum sodium <135 mmol/l), there is relative or absolute excess of body water. In both hypernatraemia and hyponatraemia, total body sodium may be increased, decreased or unchanged. It is a reasonable assumption that hyponatraemia and hypernatraemia contribute to neurological morbidity in sick newborn babies, though quantification of the effect, particularly in preterm babies, is difficult. Brain cell volume is affected by acute changes in extracellular tonicity. The regulation of cell volume following cell swelling or shrinkage in response to changes in extracellular tonicity is brought about by the accumulation or loss of inorganic ions and organic solutes. Compensatory changes in electrolyte content occur rapidly, so that, during acute exposure to hypertonicity, there is a rapid movement of electrolytes into the cell, in favour of water retention. Adaptation to chronic hyperosmolar states occurs by increasing the concentration of intracellular organic osmolytes (Strange 1993). These include polyols (sorbitol, myoinositol), certain amino acids (taurine, alanine, proline) and methylamines (betaine, glycylphosphorylcholine).

Loss of organic osmolytes occurs more slowly than movement of electrolytes. If chronic hyperosmolality is corrected rapidly, the influx of water into the cell continues, resulting in cell swelling and cerebral oedema. Cell swelling can lead to occlusion of blood flow, hypoxia and release of cytotoxic neuroexcitatory amino acids. Conversely, an acute fall in serum sodium concentration will first lead to the movement of water into cells and the development of intracellular oedema and brain swelling. Over a period of time, the concentration of intracellular osmolytes decreases, so as to favour the movement of water out of the cell. If extracellular hypotonicity is then corrected rapidly, the continued movement of water out of the cell will result in brain shrinkage.

Although the timescale over which the human brain adapts to alterations in tonicity by increasing or decreasing intracellular organic osmolytes is not clearly established, a chronic imbalance in tonicity should probably be corrected slowly, over at least 48–72 hours. The management of acute imbalance may be quicker. If hypernatraemia has developed rapidly, over a period of hours, reducing the serum sodium by 1 mmol/l/h appears safe. If hypernatraemia develops slowly, over a period of days, the rate of reduction in serum sodium should not exceed 0.5 mmol/l/h.

Proton magnetic resonance spectroscopy provides a non-invasive direct means of quantifying the organic osmolyte response to disturbances in osmolality. Lee et al. (1994) reported a 44% increase in cerebral osmolyte content in a child with chronic hypernatraemia (serum Na 195 mmol/l) that returned to normal 36 days after start of therapy. We have found a normal cerebral myoinositol 8 days after the start of therapy in a term neonate in whom hypernatraemia (serum Na 173 mmol/l) developed over a period of 8 days (unpublished data).

When attempting to establish the cause of hyponatraemia or hypernatraemia, assess the change in bodyweight in conjunction

with the clinical context. If a baby gains weight in the first days after birth at a time when weight loss would be anticipated and the serum sodium concentration is normal, isotonic expansion of the extracellular compartment has occurred and sodium and water balance is positive, at a time when it should be negative (Bétrémieux et al. 1995). Hyponatraemia with weight loss or inadequate weight gain suggests sodium depletion. Hypernatraemia with weight loss suggests dehydration; hypernatraemia with weight gain suggests sodium and water overload. Hyponatraemia due to water excess responds to water restriction but should not detract from treatment of the underlying cause. Hyponatraemia due to sodium deficit requires an increase in sodium intake, but, once body stores have been replenished, this should be reduced to maintenance requirements.

Hypernatraemia

In extremely preterm babies, hypernatraemia occurring in the first few days of postnatal life is usually due to excessive transepidermal water loss, possibly compounded by sodium administration in excess of excretory capacity. As this is a situation in which hypernatraemia may escalate rapidly, it should be treated promptly by increasing the volume of infused fluid, avoiding an excessive sodium intake, avoiding or treating hyperglycaemia and redoubling efforts to reduce insensible water loss.

Hypernatraemia arising in otherwise healthy, breastfed, full-term neonates is well described. The incidence has been variably reported because of differences in methods of ascertainment. Oddie et al. (2001) in a large population-based survey describe an occurrence of 7.1/10 000 breastfed infants. Laing and Wong (2002) report an occurrence of 14.4/10 000 infants in a single large centre, and Manganaro et al. (2001) 276/10 000 breastfed hospital admissions. Some authors cite the finding of a high urinary sodium concentration in the infant and a high breast milk sodium concentration as evidence that the condition is due to an excessive sodium intake (Bajpai et al. 2002). In fact, breast milk sodium is inversely related to breast milk volume (Neville et al. 1988). The term neonate who has had an inadequate intake of breast milk is usually both dehydrated and sodium-depleted. Volume depletion, by stimulating the renin-angiotensin-aldosterone system (RAAS), would normally reduce the urinary loss of sodium. The explanation for the seemingly paradoxical occurrence of a high urinary sodium concentration is that severe dehydration initiates a compensatory natriuresis in many mammalian species, including humans, and is a homeostatic response that serves to protect against hypernatraemia and hyperosmolality (McKinley et al. 2000). This dehydration-induced natriuresis is a physiological response that occurs even in the sodium-restricted state and appears to be mediated by osmoreceptor-stimulated oxytocin release (Huang et al. 1996). Hypernatraemia secondary to salt poisoning is distinguished by a high fractional excretion of sodium and absence of weight loss (Coulthard and Haycock 2003).

Management of hypernatraemic dehydration

Mild hypernatraemic dehydration may be corrected by enteral feeding. If intravenous rehydration is necessary 0.9% saline with glucose 5% or 10%, followed by 0.45% saline with glucose 5% or 10%, should be used (Laing and Wong 2002), and not hypo-osmolar salt-poor fluid. Milk feeds should be continued except where a specific contraindication exists. If there are signs of circulatory compromise administer an initial resuscitation volume of 20–30 ml/kg of normal (0.9%) saline over 30–60 minutes. Then calculate the initial infusion rate as follows:

1. Estimate daily maintenance fluid volume (M) in ml.
2. Estimate the total deficit (D) in ml. If the serum sodium is 149–169 mmol/l, aim to administer the deficit over 2 days ($T = 2$); if the serum sodium is 170 mmol/l or above, aim to administer the deficit over 3 days or more ($T = 3$ or more).
3. Calculate the initial infusion rate in ml/h as $[M + D/T]/24$.

Check serum electrolytes and blood glucose 1 hour after starting therapy, and then 4-hourly for 12 hours. If the serum sodium is falling at a rate greater than 0.5 mmol/l/h, reduce the rate of infusion. Aim to reduce the serum sodium at a rate not exceeding 12 mmol/l/day (see above). Too rapid correction of hypernatraemia can cause cerebral oedema, convulsions and permanent brain injury. Extremely severe hypernatraemia (serum sodium greater than 200 mmol/l) requires correction by peritoneal dialysis.

Hyponatraemia

The serum sodium concentration at birth reflects the maternal value. Often, a low serum sodium concentration at birth suggests that the mother has received a large volume of salt-poor intravenous fluid during labour, or consumed large volumes of water, resulting in an excess transfer of water to the baby. Labour ward policies should avoid the use of fixed-concentration solutions for intrapartum drug administration, as an increase in dose will result in increased infusion volume. Newborn hyponatraemia has also been described following maternal diuretic and laxative abuse and in pre-eclampsia. Dilutional hyponatraemia is more common than sodium depletion in neonatal intensive care (see following section). Sodium loss may be renal (e.g. secondary to diuretic use, polyuric phase of recovery from renal failure) or gastrointestinal. Chronic sodium loss will first be accompanied by extracellular volume contraction, poor weight gain and a normal serum sodium concentration. Hyponatraemia is a late sign. Common causes of neonatal hyponatraemia are listed in Table 18.8. Endocrine causes of hyponatraemia are discussed in Chapter 34 part 2.

Management of hyponatraemia

In acute severe hyponatraemia (serum sodium <120 mmol/l), particularly if associated with neurological signs, the intravenous infusion of 3% sodium chloride may be justified. The rate of correction should not exceed 1 mmol/l/h and the infusion of 3% sodium chloride should be stopped before a normal serum sodium is reached. As 3% sodium chloride contains approximately 0.5 mmol/ml, the infusion of 1 ml/kg will raise the serum sodium by 1 mmol/l (if ECF volume is 50% of body weight; in extremely preterm babies ECF volume may be higher). Hence the rate of infusion of 3% sodium chloride should never exceed 1 ml/kg/h.

Hyponatraemia due to sodium depletion should be managed with an increased sodium intake until the deficit is corrected. Dilutional hyponatraemia requires a reduction in fluid intake (see section below and Table 18.5).

Appropriate and inappropriate antidiuretic hormone secretion

The release of antidiuretic hormone (ADH) (arginine vasopressor (AVP)) is stimulated by a rise in osmolality and by baroreceptors located in the cardiac atria, aorta and carotid sinus. ADH has two principal actions: to increase the reabsorption of water, and vasoconstriction, contributing to the maintenance of blood pressure (BP). The pressor effect of ADH is one of the mediators through which central arterial BP is maintained, and both hypovolaemia and hypotension will result in a rise in circulating ADH (Dunn et al.

Table 18.8 Causes of hyponatraemia in the newborn

Primary water excess
Excess intake
To mother: large intrapartum infusion of sodium-free fluid To baby: excessive intravenous intake
Impaired excretion
Intrinsic renal failure Indometacin/ibuprofen Appropriate or inappropriate antidiuretic hormone secretion Adrenocortical failure
Primary sodium depletion
Insufficient intake
Maternal laxative or diuretic abuse Use of non-sodium-supplemented donor breast milk for preterm babies
Excessive loss
Renal
<i>Diuretics, including xanthines</i>
<i>Tubular dysfunction</i>
Pyelonephritis Nephrotoxic agents Obstructive uropathies
Endocrine
Salt-losing forms of congenital adrenal hyperplasia Hypoadosteronism
Gastrointestinal
External
Vomiting Stoma losses
Central nervous system
External drainage of cerebrospinal fluid in posthaemorrhagic hydrocephalus Cerebral salt wasting
Mixed
Water excess and sodium depletion
Sodium and water depletion treated with continued infusion of sodium-free fluid Chronic lung disease treated with long-term diuretic therapy
Water excess disproportionate to whole-body sodium excess
Congestive cardiac failure Liver failure
Nephrotic syndrome

1976). Under experimental conditions, a rise in ADH occurs when intravascular volume falls by about 10% (Dunn et al. 1976). Little is known of setting of baroreceptor responses in the human preterm newborn, though a doubling of urinary AVP has been described after 10% blood loss in a 26-week, 800-g infant (Rees et al. 1984a).

It has been suggested that the syndrome of inappropriate ADH (SIADH) secretion occurs frequently in the newborn (Rees et al. 1984a). Elevated ADH and hyponatraemia are certainly common in acutely ill infants. However, the maintenance of central BP overrides the defence of tonicity, as shown in experiments on human volunteers in whom progressive salt depletion was induced by a salt-free diet and vigorous sweating (McCance 1936) but water intake was unrestricted. Whole-body sodium depletion was initially accompanied by isotonic contraction of the extracellular compartment and rapid weight loss. With increasing depletion of the intravascular compartment, baroreceptor-stimulated ADH-induced water reabsorption slowed the rate of weight loss but at the cost of a fall in plasma osmolality. In such a situation, the release of ADH is not inappropriate for volume status. This effect, namely an ADH response appropriate to intravascular volume status, probably underlies the impaired water excretion seen in ill infants.

In a large prospective study, Gerigk et al. (1996) found that, although plasma osmolality was lower in acutely ill infants and children, compared with a control group, both ADH and plasma renin activity were raised, indicating activation of the RAAS. The intravenous infusion of isotonic saline resulted in a better reduction in ADH and plasma renin activity when compared with hypotonic saline and oral fluid, suggesting that ADH was appropriately elevated in response to a reduced intravascular volume.

The recognition of an inadequate intravascular volume can be difficult. In the study described above (Gerigk et al. 1996), only a third of infants and children had overt signs of dehydration. Newborn babies are at risk of intravascular volume depletion (Wardrop and Holland 1995) from immediate cord clamping, which may lead to a reduction in blood volume by as much as 50% when compared with late clamping (Linderkamp et al. 1992) and subsequently from frequent blood sampling. As the normal range for BP in the newborn is wide and BP correlates poorly with blood volume (Barr et al. 1977; Bauer et al. 1993), BP measurements cannot be relied upon to detect hypovolaemia. Careful attention should be paid to assessment of the circulation using central venous pressure monitoring (Skinner et al. 1992), capillary refill time, the core-peripheral temperature difference and Doppler echocardiographic assessments (Pladys et al. 1994; Evans 2003). The core-peripheral temperature difference correlates with circulating AVP (Lambert et al. 1990).

Postoperative hyponatraemia is similarly a consequence of unrecognised intravascular volume depletion and continuing provision of salt-poor fluid, with ADH-driven water retention. Glucose in 0.9% NaCl (Judd et al. 1987) (Table 18.5), not colloid, is the preferred fluid (So et al. 1997) for intraoperative and postoperative support. Once water retention and hyponatraemia have occurred, water restriction is necessary to correct the hyponatraemia safely.

True inappropriate ADH secretion is probably rare in the newborn (Haycock 1995). This diagnosis should be made only in accordance with the classic criteria of Bartter and Schwartz (1967) when hyponatraemia exists with normovolaemia, normal BP, normal renal and cardiac function, evidence of continuing sodium excretion and urine that is not maximally dilute. In the newborn, SIADH has been described in acute brain injury and central nervous system infection and following maternal substance abuse (Winrow et al. 1992).

In pathological circumstances such as heart or liver failure, hypotension occurs together with an expanded extracellular

compartment and there is whole-body sodium excess despite hyponatraemia. Myocardial dysfunction may contribute to impaired water excretion. The pathophysiology of disordered salt and water balance in severe chronic lung disease is complex. Hyponatraemia with clinical signs suggestive of an expanded extracellular compartment may reflect whole-body sodium depletion by chronic diuretic therapy and suboptimal nutrition together with impaired free water clearance (Hazinski et al. 1988) driven by abnormal transmural pressure gradients leading to effective central hypotension and increased AVP release. During acute exacerbations of respiratory failure associated with air trapping, a decrease in central venous return, pulmonary blood flow and left atrial filling will lead to a similar situation (Rao et al. 1986). A degree of pulmonary hypertension is an almost invariable accompaniment of chronic lung disease, and fluid retention may be attributable to poor cardiac function. Steroid therapy is another possible cause of compromised cardiac function (Brand et al. 1993; Haney et al. 1995), though now rarely used in chronic lung disease.

Common pharmacological influences on fluid balance

Indometacin and ibuprofen

Indometacin and ibuprofen are non-selective cyclo-oxygenase (COX) inhibitors that promote patent ductus arteriosus closure through inhibition of prostaglandin synthetase. Indometacin is also administered antenatally as a tocolytic, and to reduce liquor volume in polyhydramnios. These substances reduce sodium excretion by enhancing tubular reabsorption. In the preterm infant COX inhibition appears to lower glomerular filtration rate, an effect that may reflect dependence on renal prostaglandins to maintain an adequate renal blood flow in the face of high RAAS activity (Oliver et al. 1980). As amelioration of the oliguric response to indometacin has been described in the presence of an AVP V_2 -receptor antagonist (Walker et al. 1994), AVP stimulation may be another mode of action.

A temporary reduction of sodium and water excretion is described in all reports of babies given indometacin. Ibuprofen, a licensed product, has largely replaced indometacin for pharmacological duct closure. Although meta-analyses suggest that ibuprofen has fewer side-effects than indometacin (Ohlsson et al. 2010), oligohydramnios and neonatal renal failure have been described after maternal exposure (Bavoux 1992; Kaplan et al. 1994). Suggestions that the simultaneous administration of furosemide or dopamine

eliminates the renal side-effects of indometacin without reducing efficacy of duct closure (Yeh et al. 1982) have not been substantiated (Fajardo et al. 1992; Barrington and Brion 2002).

With careful management salt and water retention and dilutional hyponatraemia can be avoided. If indometacin is to be used in a dose of 0.2 mg/kg 12-hourly, or if the baby is extremely immature, restrict sodium and water intake by 30%. Indometacin, 0.1 mg/kg 24-hourly (Rennie and Cooke 1991), and ibuprofen are less likely to result in adverse renal effects. Careful monitoring of urine output, serum sodium and weight gain are advisable whenever COX inhibitors are used.

Glucocorticoid steroids

The synthetic glucocorticoids dexamethasone and betamethasone, widely used in perinatal medicine, have a number of potent actions. They are gene transducers as well as having direct effects at the level of the cell membrane. They increase β_2 -receptor density, antioxidant levels and the density of Na^+/K^+ -ATPase, affect a variety of cytokines and growth factors, enhance surfactant production, increase clearance of lung liquid, suppress inducible nitric oxide synthase and are catabolic. A temporary inhibition in growth is well documented during therapy and this often results in a rise in blood urea.

The abundance of Na^+/K^+ -ATPase is regulated by glucocorticoids (Celsi et al. 1991) in an age-dependent manner (Celsi et al. 1993). In rats, betamethasone will increase Na^+/K^+ -ATPase mRNA in the kidney during infancy, but not during fetal life, nor in adults. In contrast, lung tissue Na^+/K^+ -ATPase is maximally induced by glucocorticoids during the perinatal period. The inference is that glucocorticoids interact with other transcriptional factors, expressed in an age-dependent fashion, to activate the genes for Na^+/K^+ -ATPase so that different tissues have different periods of sensitivity to glucocorticoid regulation. Glucocorticoids enhance renal tubular regulation of sodium balance, potentiate atrial natriuretic peptide stimulation of cGMP production (Hayamizu et al. 1994) and enhance the maturation of renal acidification (Baum and Quigley 1993). In addition to the well-known effects on the lungs, antenatal exposure to dexamethasone accelerates the maturation of renal function in human preterm newborns (Al-Dahan et al. 1987) and induces both Na^+/K^+ -ATPase and Na^+ channels in lung epithelial cells, thus facilitating the clearance of lung liquid (O'Brodovich et al. 1993). This may underlie the seemingly paradoxical effect of glucocorticoids in triggering a diuresis in the fluid-retaining baby with chronic lung disease (Schrod et al. 1991; Greenough et al. 1993).

Introduction

Successful care of the newborn depends on understanding the pathophysiology of the conditions affecting the baby. To follow changes in clinical condition, and the effects of treatment, it is essential that we are able to monitor the progress of the baby.

There are many devices used in the monitoring of the newborn baby. Many are well established and considered standard in all cases, e.g. heart rate, while others are still finding their place in routine clinical care of certain groups of babies, e.g. cerebral

function monitors. There are several areas of debate, e.g. whether transcutaneous partial pressure of oxygen (PO_2) or saturation gives the better information, and also about when invasive monitoring, such as intra-arterial blood pressure (BP), should be used.

If information is collected from monitors it must be interpreted and then acted upon. This requires not only knowledge of the underlying physiology, but also at least a basic understanding of how the monitors work. In particular it is important to know the limitations of the devices and the circumstances in which they become unreliable.

Electrical safety

With the large number of devices attached to babies, electrical safety is of paramount importance and all equipment must conform to strict regulations.

The Medicines and Healthcare products Regulatory Agency (MHRA) is a government body with a responsibility to ensure safety of all medical devices. This body ensures that all European Union Directives on safety of medical equipment are implemented. In essence all devices must carry a CE mark as a sign of conformity, which includes assurance that the device meets the general requirements for safety of medical electrical equipment. This also applies to any equipment used for research. Current standards for medical equipment are available on the MHRA website.

There has been debate about whether mobile phones, and other equipment capable of transmission, can interfere with medical devices and monitoring equipment in particular. The MHRA has included recommendations on the use of transmitting devices close to patient monitors (Table 19.1).

The British Association of Perinatal Medicine has published recommendations for units carrying out intensive and high-dependency care of the newborn (BAPM 2001). Units must have an agreed policy for the purchase and maintenance of all equipment, as well as for staff support and training. This must be done in consultation with a department of medical physics and be supported by an adequate budget.

Cardiovascular monitoring

Heart rate and ECG

The electrodes used to obtain the electrocardiogram (ECG) should be placed lateral enough on the chest to minimise any shadow on X-ray. Correct positioning is important if these leads are also used to produce a respiratory trace by impedance changes.

The displayed trace is not of diagnostic quality and a full 12-lead ECG must be requested if an arrhythmia is suspected (Ch. 28, Appendix 3).

Changes in the ECG pattern can indicate conditions such as hyperkalaemia and myocardial ischaemia. A reduction in the size of the complexes may be an early sign of pulmonary air leak or cardiac tamponade (Merenstein et al. 1972).

Heart rate can be derived and displayed from the ECG. With many multiparameter monitors, the heart rate can also be obtained from the BP trace, removing the need to stick electrodes on to fragile skin. Access to the ECG signal does have the advantage that it is possible to check artefacts such as an artificially high heart rate due to 'double counting' of the QRS and T waves.

Tachycardia is associated with haemorrhage, hypovolaemia or inadequate analgesia. Bradycardia in the ventilated infant is often a sign of a blocked endotracheal tube, while in the self-breathing baby it is usually an indicator of apnoeic episodes.

Echocardiography

Echocardiography is used for the assessment of structural heart defects as well as helping to detect, and determine management of, the patent ductus arteriosus. It can also help in the assessment of ventricular function following asphyxia and in chronic lung disease. Although echocardiography may help guide the use of volume replacement or inotrope support in a baby with hypotension, there is, as yet, no evidence that its routine use in monitoring the newborn baby has any impact on long-term outcome.

Table 19.1 Medicines and Healthcare products Regulatory Agency recommendations on use of transmitting equipment in hospitals

RISK OF INTERFERENCE	TYPE OF COMMUNICATION SYSTEM	RECOMMENDATION
High	Analogue emergency service radios Private business radios (PBRs) and PMR446, e.g. porters' and maintenance staff radios (two-way radios)	Use in hospitals only in an emergency, never for routine communication Minimise risks by changing to alternative lower risk technologies
Medium	Cellphones (mobile phones) Terrestrial trunked radio system (TETRA) Laptop computers, palmtops and gaming devices fitted with higher power wireless networks such as GPRS and 3G HIPERLAN	A total ban on these systems is not required and is impossible to enforce effectively Should be switched off near critical care or life support medical equipment Should be used only in designated areas Authorised health and social care staff and external service personnel should always comply with local rules regarding use
Low	Cordless telephones (including DECT) Low-power computer wireless networks such as WLAN systems and Bluetooth	These systems are very unlikely to cause interference under most circumstances and need not be restricted

Perfusion

Tissue survival depends on both oxygenation and the blood flow (perfusion) through the capillary bed. Monitoring tissue perfusion is important for early recognition of circulatory failure and in assessing response to therapy.

Blood pressure

Normal values for BP in the neonate are shown in [Appendix 4](#). Perfusion is dependent on the systemic BP but, particularly in the first 48 hours of postnatal life, there is no good correlation between level of BP and tissue perfusion ([Groves et al. 2008](#)). During the first days of life many aim to maintain a mean arterial BP around a value equal to the gestational age in weeks. Use of gestational age criteria may lead to overtreatment, which has been associated with adverse outcome. In any particular baby, the level used to diagnose significant, and symptomatic, hypotension will depend on other clinical features of perfusion including renal function, acid-base state and oxygenation. There is no indication to treat low BP where there is clinical evidence of good perfusion ([Dempsey et al. 2009](#)).

BP can be monitored directly with transducers attached to arterial lines. These need calibrating to zero and changes in position of the transducer relative to the heart may alter the reading. The calibration and position should be checked if there has been a sudden change in BP. Visual display of the waveform is important in assessing reliability, as damping of the arterial trace affects systolic and diastolic BP. Mean pressure remains more reliable but even this can become unreliable when the trace is damped ([Cunningham et al. 1994a](#)).

Non-invasive oscillometric methods significantly overestimate BP at the lower end and are poor at detecting hypotension. They should not be used to verify low readings from arterial lines. Mean BP is taken as the point where the oscillations in the cuff are maximum and, although related to the true mean BP, this value will differ from that obtained from an intra-arterial line ([Diprose et al. 1986](#)).

As changes in BP are not always a good indication other methods are needed to help assess tissue perfusion.

Skin perfusion

In low-flow states, blood supply in the skin is reduced to protect perfusion of vital organs. Skin blood flow is used as a marker of overall perfusion but it is also affected by the thermal environment ([Gorelick et al. 1993](#)).

Capillary refill time correlates poorly with hypovolaemia in children ([Leonard and Beattie 2004](#)). Normal values for neonates, nursed in different thermal environments, have been published ([Strozik et al. 1997](#)), and, in general, the skin reperfuses in less than 3 seconds. Capillary refill is better estimated on the skin of the forehead or chest rather than the toes, but it is an unreliable indicator of cardiovascular status in neonates ([LeFlore and Engle 2005](#)).

Decreasing skin blood flow results in a widening of the central-peripheral temperature gap. This can indicate hypovolaemia, or a decrease in venous return, before the BP falls ([Lambert et al. 1998](#)). Delay in establishing vasomotor tone makes these changes an unreliable measure of tissue perfusion in the very-low-birthweight infant immediately after birth ([Osborn et al. 2004](#)). In the absence of other indicators of hypovolaemia, such as a rising heart rate, a widening temperature gap is more likely to be due to cold stress ([Lyon et al. 1997](#)).

Central venous pressure

Central venous pressure (CVP) can be measured with an umbilical venous catheter in the right atrium. Close attention to maintaining the position of the transducer relative to the heart is essential, and the monitor must be calibrated to zero frequently. There is little information on the use of CVP in the newborn baby. A value of zero in the ventilated neonate is usually associated with other signs of hypovolaemia ([Skinner et al. 1992](#)).

Lactate

Measurement of lactate can be incorporated into blood gas or glucose analysers. Accumulation of lactate, implying increasing anaerobic metabolism, occurs in sepsis and with a reduction in tissue perfusion. There is poor correlation with arterial pH and, in the absence of a raised lactate, a metabolic acidosis is unlikely to be due to hypoperfusion. Values above 3 mmol/l soon after birth are abnormal and serial measurements can provide important prognostic information in ill, ventilated neonates ([Deshpande and Ward Platt 1997](#)).

Lactate levels are elevated following asphyxia. Levels below 5 mmol/l at 30 minutes of age have been followed by a good outcome ([da Silva et al. 2000](#)), while those above 7.5 mmol/l have been associated with moderate or severe encephalopathy with a sensitivity of 94% and specificity of 67% ([Shah et al. 2004](#)). Persistently high lactate levels, above 10–15 mmol/l, suggest an inborn error of metabolism ([Ch. 34.3](#)).

Other measures of perfusion

Change in urine output, monitored using pre-weighed nappies or cotton wool balls, is an insensitive marker of tissue perfusion, with volumes decreasing only after a fall in BP. Normal urine output is discussed on [Ch. 35.1](#).

Venous oxygen tension or saturation, measured in blood taken from a catheter passed through the foramen ovale into the left atrium, may be a better indicator of oxygen delivery but is not in routine use ([O'Connor and Hart 1994](#)). Near-infrared spectroscopy (NIRS) ([Yoxall and Weindling 1996](#)) and gastric intramucosal pH measured by tonometry ([Campbell and Costeloe 2001](#)) are techniques not yet applicable to everyday clinical use. Using echocardiography to measure flow in the superior vena cava (SVC) gives a better reflection of cerebral blood flow than does cerebral artery Doppler measures or mean BP ([Evans et al. 2002](#)). Low SVC flow has been associated with early neonatal death and/or severe intraventricular haemorrhage ([Miletin and Dempsey 2008](#)).

Taking low SVC flow as the indicator of poor perfusion, there was poor correlation between capillary refill time, mean BP and urine output with SVC flow. However combining a capillary refill time of >4 seconds with a serum lactate concentration of >4 mmol/l increased the specificity of detecting a low SVC flow state to 97% as well as improving the positive and negative predictive values ([Miletin et al. 2009](#)).

Respiratory system monitoring

Respiration

There are several methods used for respiratory monitoring, and these are discussed in [Ch. 27.4](#). Respiration monitors are used routinely to detect apnoea. They add little extra benefit to the monitoring of the ventilated baby, where more useful information is obtained from the ventilator.

The relationship between apnoea, bradycardia and desaturation is complex. In the majority of episodes, apnoea or hypoventilation is the initiating event, causing a fall in oxygen saturation, which in turn triggers a reflex bradycardia (Adams et al. 1997).

Apnoea monitors alone have been shown to miss significant episodes of both apnoea and bradycardia (Southall et al. 1983). In the absence of monitors that measure airflow, mixed or obstructive apnoea will only be identified by the accompanying bradycardia and desaturation.

An apnoea monitor should be attached to all spontaneously breathing babies who have either apnoeic attacks or respiratory disease likely to be complicated by apnoea. However, if there are true concerns, then respiratory monitoring should always include a measure of heart rate and oxygen saturation.

Oxygen

Knowledge of the partial pressure of oxygen in arterial blood (P_{aO_2}) is essential in intensive care. This can be measured intermittently, by arterial puncture or sampling from an indwelling catheter, or continuously, by use of an intravascular transducer. The frequency of sampling depends on the clinical condition of the baby and on the reliability placed on values obtained from continuous oxygen monitors.

Arterial puncture

This is painful, and crying alters the P_{aO_2} (Dinwiddie et al. 1979). A patent ductus arteriosus may result in a higher P_{aO_2} in the right arm and head/neck compared with other areas of the body.

Capillary and venous samples

Results from arterialised capillary samples can be misleading if the baby is poorly perfused or the blood not free-flowing. They should not be used in the assessment of the acutely ill baby. Capillary and venous samples underestimate P_{aO_2} significantly and should not be used to predict arterial values in neonates (Courtney et al. 1990). Neither should be used in the assessment of the acutely ill neonate but both show a good correlation with acid-base state and P_{CO_2} in the stable baby (Yildizdaş et al. 2004).

Indwelling arterial lines

Indwelling arterial lines allow repeated sampling without disturbing the infant and can be used for continuous BP monitoring. Further information on the techniques used to insert arterial lines, and their complications, can be found in Chapter 44.

Umbilical artery catheter

The tip of the umbilical artery catheter is positioned in the descending aorta (Ch. 44). High catheters (above the diaphragm) have fewer complications (Ch. 44) than those positioned low (just above the aortic bifurcation), and can remain in situ for longer (Barrington 2000a). Low-dose heparin (1 unit/ml) added to the infusion fluid reduces the risk of catheter blockage (Barrington 2000b).

X-ray is needed to confirm the site of the tip (Ch. 43) but accuracy of initial positioning has been shown to be improved, reducing significantly the need for further manipulation of the line, using the formula (Wright et al. 2008):

$$\text{insertion length (cm)} = (4 \times \text{birthweight (kg)}) + 7$$

Peripheral artery catheters

The radial or posterior tibial arteries are commonly used, but the ulnar, dorsalis pedis and axillary arteries are alternatives (Ch. 44). The brachial and femoral arteries should be avoided.

Complications are rare, but vasospasm and thrombus formation can cause major problems, even when collateral circulations are intact. Low-dose heparin must be added to the infusion.

The Allen test is used to test the integrity of the palmar arches before either the radial or ulnar artery is cannulated but, even in adults, this has not been shown to be accurate in predicting post-cannulation hand ischaemia (Barone and Madlinger 2006). This test is even less reliable in the newborn, mainly because of technical difficulties. It is essential that the limb is observed closely, and the catheter removed at the first sign of impaired perfusion.

Total occlusion of the artery may persist after the catheter is removed. For this reason, the ulnar artery should not be used if the radial artery in that hand has been cannulated previously.

Continuous intravascular blood gas monitoring

With intermittent sampling, major fluctuations in condition may be difficult to follow. Increasing the frequency of sampling introduces significant blood loss in small infants.

Continuous intravascular P_{aO_2} , P_{CO_2} , pH and temperature monitoring are possible (Goddard et al. 1974; Morgan et al. 1999). Although reliable, the accuracy of these electrodes deteriorates with time as a result of fibrin deposition. The use of indwelling blood gas monitoring electrodes is now very limited; most units use non-invasive monitors for oxygen and carbon dioxide monitoring, with arterial catheters for BP measurement and sampling.

Transcutaneous monitoring

These probes contain a heater that arterialises the blood in the skin. Oxygen diffuses through a membrane into the electrode, where it is reduced, setting up an electric current, the size of which is related to the partial pressure of the gas being monitored. This is displayed as the transcutaneous value, e.g. transcutaneous P_{O_2} (T_{CO_2}).

Calibration takes several minutes and, once sited, the electrode takes around 15 minutes to equilibrate. The heat from the probe will burn the skin if not moved every 2–4 hours (Golden 1981; Poets et al. 1991). The combination of resiting and recalibration can mean that the sensor is not recording on the baby for substantial periods of time.

Falsely low readings are obtained if the probe is placed over poorly perfused skin, e.g. a bony surface (Takiwaki et al. 1991), if the infant lies on the electrode or if there is poor peripheral circulation (Vyas et al. 1988). Falsely high readings occur when there is poor contact with the skin, allowing air to get under the electrode.

There is a larger difference between T_{CO_2} and P_{aO_2} in older infants (Poets and Southall 1994), but within infants the ratio between T_{CO_2} and P_{aO_2} remains constant. Although absolute values may not be accurate, the trend in T_{CO_2} can still give useful information.

The sensitivity and specificity of transcutaneous monitors at detecting hypoxia ($P_{aO_2} < 6.6$ kPa) have been estimated at 85% and 97%, respectively. For hyperoxia ($P_{aO_2} > 13.3$ kPa), the sensitivity is 87% and specificity 89%. This means that the monitors will miss approximately 15% of both hypoxic and hyperoxic events, defined by these limits (Poets and Southall 1994).

Target values for T_{CO_2} depend on maturity, severity of illness and underlying diagnosis. It is common practice in preterm infants to aim for T_{CO_2} between 6 and 10 kPa.

Saturation monitoring

Pulse oximetry is now the standard method of oxygen monitoring. It is based on the principle that oxygenated haemoglobin absorbs light in the infrared region of the spectrum (850–1000 nm) while deoxygenated haemoglobin absorbs light in the visible red band (600–750 nm). The ratio of the light absorbed at two different wavelengths correlates with the proportions of oxygenated and deoxygenated haemoglobin in the tissues. The oximeter detects pulsation, which ensures that it is measuring only light absorbed by the haemoglobin in the blood vessels.

Pulse oximeters are easy to use, require no calibration and give immediate information. They are prone to artefact, and users must be aware of the many problems that can result in incorrect readings.

Strong ambient light and light bypassing the tissues cause an optical shunt, which is a common cause of artefact. Poor perfusion will affect the function of the oximeter, with most needing a pulse pressure of >20 mmHg (Morris et al. 1989; Falconer and Robinson 1990) or a systolic BP >30 mmHg (Severinghaus and Spellman 1990). Tight tape around the probe can affect the signal by impairing arterial pulsation, and can cause scarring and deformation of the hand or foot.

On the same baby, two oximeters may give different readings (Grieve et al. 1997). Some display functional saturation and others fractional saturation. The latter allows for levels of carboxyhaemoglobin and methaemoglobin, and is, in general, 2% lower.

Movement artefact is common and often makes interpretation of readings difficult, as well as being the most common cause of false alarms. It is important to check that the light plethysmography waveform shows a good-quality signal (Poets and Southall 1994). Another method of validation is to compare the pulse rate measured by the oximeter with that from an ECG monitor (Poets and Stebbens 1997). The readings are reliable only when the two heart rates are the same. In practice this usually means that the rates are within 5–10 beats of each other.

Figure 19.1 shows a typical trace with both heart rates. There is initially a period of poor agreement between the rates, and the dips in the saturation are caused by artefact. There then follows a period of good agreement, with reliable saturation readings.

Recent developments in pulse oximetry have reduced the false-alarm rates. In particular, instruments using the Masimo Signal extraction technology have been shown to identify true desaturations and bradycardias at least as reliably as a conventional oximeter but with 93% fewer false alarms (Bohnhorst et al. 2000). There is also a reported improvement in performance in clinical situations in which extreme motion artefact is likely (Sahni et al. 2003).

Detection of hypoxia

Oximeters use 'look-up' tables based on data from healthy adults to convert light absorption to saturation. Low levels have been derived by extrapolation from higher values and as a consequence these monitors underestimate the true degree of hypoxaemia.

Fig. 19.1 Artefact on oxygen saturation recording shown by lack of agreement of heart rate traces.

Sensitivity and specificity for the detection of hypoxaemia have been estimated at 92% and 97%, respectively (Poets and Southall 1994).

Hyperoxia

The shape of the haemoglobin dissociation curve means that oximeters have a low sensitivity to hyperoxia, with small shifts in saturation reflecting large changes in P_{O_2} . With an upper alarm limit set at 95%, newer instruments detect hyperoxia (>10.6 kPa) with a sensitivity of around 95% but a specificity of only 26–45%. Lowering the alarm limits improves the sensitivity but decreases the specificity even further (Bohnhorst et al. 2002).

Normal values for oxygen saturation

A functional saturation below 95%, obtained repeatedly while the infant is breathing regularly, should be regarded as abnormal, irrespective of age. Occasional falls in saturation below 80% are probably normal during the first 6 months of life (Poets 1999). However, there are no data that tell us at what baseline saturation level intervention should be considered or how often, or for how long, and to what nadir saturation may be allowed to fall. We know a lot about saturation monitoring in normal babies but remain uncertain about how to apply this technology to infants with respiratory disease.

It is difficult to recommend limits for oxygen saturation in babies with lung disease (see *Monitoring the sick baby*, below). Applying data from normal babies may increase their exposure to inspired oxygen, which in itself may be damaging (Anonymous 2000a; Saugstad 2001; Tin et al. 2001), while low saturations in infants have been associated with acute life-threatening events (Iles and Edmunds 1996).

Data from the SUPPORT study in infants under 28 weeks' gestation randomised to a low (85–89%) or high (91–95%) target range of oxygen saturation has shown no difference in the composite outcome of severe retinopathy or death. However there was an increase in mortality and a substantial decrease in severe retinopathy among survivors in the low target range (SUPPORT study group 2010). BOOST-II was an MRC funded randomised controlled trial comparing the effects of targeting arterial oxygen saturations in babies less than 28 weeks' gestation at the same levels as in the SUPPORT study. The composite primary outcome was mortality and major disability at 2 years corrected age. This study ceased recruitment following publication of the SUPPORT trial (SUPPORT 2010) showing a lower mortality in babies whose target oxygen saturation was 91–95%. A preliminary safety meta-analysis of data from SUPPORT and the BOOST trials recruiting in the UK, Australia and New Zealand confirmed this result and hence current recommendation is to target oxygen saturation at 91–95% (Stenson et al. 2011).

The higher mortality found in the SUPPORT study is of concern and until data are available from trials such as BOOST-II, many recommend that oxygen therapy be considered when baseline saturation is less than 93% (Poets 1998). The safe upper limit is uncertain but recent outcome data suggest around 95%. Infants in hospital are commonly allowed lower saturations, but, if being discharged home in oxygen, they should be maintained with a saturation above 93% (Poets 1998).

Carbon dioxide

The partial pressure of carbon dioxide (P_{CO_2}) is important in determining the adequacy of alveolar ventilation and interpreting the acid–base balance. P_{CO_2} is affected by crying, which commonly

occurs during intermittent sampling. Capillary samples are useful for monitoring stable infants with chronic respiratory problems, but care must be exercised in their interpretation (Courtney et al. 1990). Venous samples may be an acceptable alternative when monitoring trends in P_{CO_2} , but the literature is limited and even greater care should be taken in interpreting the values obtained. In the particular situation of a baby with cardiac arrest, the difference between arterial and venous P_{CO_2} is very large.

Transcutaneous CO_2 monitoring

Transcutaneous CO_2 ($TcCO_2$) is commonly combined with oxygen monitoring in the same probe. Most $TcCO_2$ electrodes work by measuring the change in pH of an electrolyte solution, separated from the skin by a hydrophobic membrane, which is permeable to carbon dioxide but not to hydrogen ions.

$TcCO_2$ is in general 27% higher than the corresponding arterial measurement, due partly to local tissue production of carbon dioxide as well as to the heating coefficient of blood. The electrodes need calibration against a known concentration of carbon dioxide every 4 hours. This can take 10 minutes, adding to the time that the probe is not in use monitoring the baby.

Over a 4-hour period, there is an upward drift in the $TcCO_2$ but overall there remains a good correlation between transcutaneous and arterial CO_2 , making it a useful trend monitor. Repeated blood gas estimations are still required, but changes in $TcCO_2$ can give early warning of developing problems, such as a blocking endotracheal tube (Fig. 19.2). In transport, $TcCO_2$ monitoring has resulted in babies arriving with lower ventilator pressures and better blood gases (O'Connor and Grueber 1998).

There are no data on normal values for $TcCO_2$. Experience with these monitors has been that each baby has an individual relationship between arterial and $TcCO_2$. These probes are more useful as a means of following trends than as a measurement of true arterial P_{CO_2} .

End-tidal CO_2 monitoring

Capnography measures the concentration of CO_2 in exhaled gas and has been used extensively in patients under general anaesthesia and in adult intensive care. Small tidal volumes, rapid respiratory rates and inhomogeneous alveolar ventilation/perfusion in neonates with lung disease have limited the use in the newborn (Hand et al. 1989). $TcCO_2$ monitoring provides a more accurate estimation of P_{aCO_2} (Tobias and Meyer 1997) and remains the preferred method of monitoring CO_2 during transport (Tingay et al. 2005).

The problem of inhomogeneous lung disease has been diminished by replacement surfactant. Studies using newer mainstream monitors, with low dead space and resistance, have shown capnography to have some place in monitoring trends in carbon dioxide (Rozycki et al. 1998). Colorimetric CO_2 detectors are useful adjuncts for airway management, especially for checking endotracheal tube placement during resuscitation (Molloy and Deakins 2006).

Acid–base balance

Monitoring of the pH, bicarbonate and base excess is important in the assessment of respiratory status. Capillary and venous samples can be used to monitor changes in acid–base state in the stable baby (Yildizdas et al. 2004) but arterial blood should be used in the assessment of the ill neonate.

Fig. 19.2 Trend graphs of an infant showing arise in transcutaneous CO_2 for several hours before a blocked tube was diagnosed. Black arrows show times when the probe was off the baby for recalibration.

Continuous online respiratory function monitoring

This is now available on most ventilators. Data are presented as numerical values, time-based waveforms of flow, volume and airway pressures, and flow/volume and pressure/volume loops. The interpretation of this information requires knowledge of how the data are obtained as well as an understanding of the underlying pathophysiology.

These monitors have been shown to reduce mortality in adults with acute respiratory distress syndrome (Anonymous 2000b). In infants, their use has reduced ventilator time (Stenson et al. 1998) and short-term morbidity (Rosen et al. 1993), although as yet there is little evidence that overall outcome is improved. Further critical evaluation is required, as not all the information used in adult trials can be obtained reliably in newborn infants.

A flow sensor, usually a hot-wire anemometer, needs to be connected directly to the endotracheal tube and this adds 1 ml to the respiratory dead space. In the smallest infants this could necessitate increased minute ventilation to maintain CO_2 elimination (Stokes et al. 1986). Data from different devices may not be comparable. Changes in gas composition affect the measurements. Pure oxygen is 12% more viscous than room air, so reducing the fraction of inspired oxygen (FiO_2) may result in an apparent increase in tidal volume (Yeh et al. 1984).

Functional residual capacity

Measurements of tidal volume and functional residual capacity (FRC) can be used to avoid high end-inspiratory and low end-expiratory lung volumes. FRC varies considerably over the course of an illness and can change rapidly with treatments such as surfactant or high-frequency oscillatory ventilation. There is presently no readily applicable method for repeated measurements of FRC that would be suitable for routine clinical use. FRC is inferred from the chest X-ray appearances and the FiO_2 required to achieve adequate oxygenation, although the relationship between the radiographic and measured lung volumes is inconsistent (Thome et al. 1998).

Leaks

There is generally some leak around the uncuffed endotracheal tubes used in newborn infants. The mean leak has been estimated at around 15% (Bernstein et al. 1995). A leak makes some of the derived data, such as compliance and resistance, unreliable (Mahmoud et al. 2009) and also complicates the interpretation of loops and waveforms. Most of the leak occurs in inspiration and is calculated as inspired minus expired volume, expressed as a percentage of the inspired volume. The displayed expired tidal volume has usually taken the leak into account and further correction is not needed.

The size of the leak only becomes important if there is a problem with ventilation. Flow-triggered ventilators are susceptible to auto-cycling in the presence of an airway leak, the rate of autocycling being proportional to the size of the leak (Bernstein et al. 1995).

Tidal volume

A healthy, spontaneously breathing term baby with no lung disease has a tidal volume of around 7–9 ml/kg bodyweight (Anonymous 1993). The ventilated infant with respiratory disease has fewer functional airspaces, and there may be regional inhomogeneity of pressure/volume characteristics within the lungs. 'Normal' tidal volumes may therefore expose parts of the lungs to excess end-inspiratory volume. Because of this, target tidal volumes are generally set around the 4–6 ml/kg range, depending on the CO_2 elimination. When there is pulmonary hypoplasia, target tidal volumes may need to be lower, as the inspiratory capacity of the lungs per unit bodyweight will be less than normal.

Some devices display tidal volume breath by breath, while others give a rolling average. Spontaneous breaths are generally smaller than ventilator breaths, so if averaging is used it will not give a true impression of the ventilator tidal volumes, if there is significant spontaneous breathing. Displayed values are not weight-corrected.

Minute ventilation

A rolling average of expired minute ventilation can be calculated and subdivided into the relative proportions attributable to ventilator and spontaneous breaths. Whether this is any more useful than looking at tidal volumes is unclear. There is no evidence that measuring minute ventilation is any more useful than monitoring transcutaneous PCO_2 .

Compliance and resistance

There are a variety of methods for deriving these data from continuous dynamic pressure/volume traces, but they are unlikely to be useful in everyday clinical practice. The values are affected by lung volume at the time of measurement and are unreliable if inappropriately short inspiratory or expiratory times are used. They are made inaccurate by leaks around the endotracheal tube. The variable nature of infant-ventilator interactions complicates their interpretation in real time.

The C20:C ratio is a derived index of lung overdistension which compares the compliance during the last 20% of inflation with that of the whole breath (Fisher et al. 1988). This index is unreliable in newborn infants because it requires a ventilator which generates a slow rise in inflation pressure, or a constant flow of gas into the lungs during inflation, and little or no air leak (Neve et al. 2000), conditions seldom met in neonatal ventilation.

Waveforms

Simultaneous time-based traces of flow, volume and pressure are the most commonly used graphical representation of respiratory function and provide the most readily interpretable information. The scaling of the graphs is important. Autoscaling should be used with caution, as changes in the size of the waveforms, due to variation in respiratory function, may be obscured by the system redrawing them on a new scale.

The time-based waveforms help in determining appropriate inspiratory and expiratory times. Figure 19.3 shows simultaneous traces of flow, volume and pressure over time from a ventilated

Fig. 19.3 Simultaneous time-based waveforms of flow, pressure and volume from a ventilated infant.

Fig. 19.4 Time-based waveforms from an infant with a modest leak around the endotracheal tube.

infant. With the onset of inflation, pressure rises to a peak and is maintained at this level for the duration of inspiration. As the pressure has risen, gas flows into the lungs and inspiratory flow (shown above the line) rises rapidly to a peak before falling to zero. No further volume passes into the lungs for the remainder of the set inspiratory time. The volume trace rises rapidly to a peak and then plateaus, with the inspired tidal volume held in the lungs until the onset of expiration. If there is an air leak around the endotracheal tube, the volume plateau is not horizontal but slopes upward from left to right (Fig. 19.4). The gradient of the slope reflects the size of the leak. Under these circumstances, the flow trace does not return

Fig. 19.5 Simultaneous waveforms from an infant with a long expiratory phase. After 1 second in expiration, expiratory flow has not quite reached zero before the onset of the next inspiration.

to zero but continues at a low level after the initial rapid rise and fall (Fig. 19.4). In the case of a very large leak, or when the endotracheal tube has slipped out of the trachea, the volume trace continues to rise steeply until it goes off the screen and the flow remains high throughout inspiration. Under these circumstances, little or no expiratory flow is seen at the onset of expiration.

At the onset of expiration, the pressure in the ventilator circuit falls to the set positive end-expiratory pressure (PEEP) level. Gas flows out of the lungs and expiratory flow (conventionally displayed below the baseline) accelerates to a peak and then falls to zero (Fig. 19.3). The volume trace falls from the inspiratory volume peak to zero. If there is an air leak around the endotracheal tube, the volume trace does not return to zero because the gas that leaked around the tube in inspiration cannot be exhaled (Fig. 19.4). Monitoring devices are usually set to re-zero the volume baseline at the onset of the next inspiratory flow. If the next inflation begins before the expiratory flow has returned to zero, gas is trapped in the lungs. This phenomenon is called occult or inadvertent PEEP (Simbruner 1986). It will impair gas exchange and occasionally may be life-threatening (Stenson et al. 1995). Inspection of the expired flow waveform allows the clinician to ensure that expiratory flow has returned to zero before the onset of the next inflation and prevent this complication. In Figure 19.5, expiratory flow has not quite returned to zero when the next inflation arrives, despite an expiration time of around 1 second.

With an obstructing endotracheal tube, the height of the peak flow on the inspiratory and expiratory flow waveforms lessens, and the width of the expiratory flow pattern broadens because the increase in airway resistance makes gas movements take longer. Excessive rain-out of humidity in the tubing can partially obstruct the bias flow in the circuit. This causes fluctuations in airway pressure, resulting in small flow oscillations at the airway, which are seen in the flow baseline at times when there should be no flow. They can result in autocycling of the ventilator, and the presence of an oscillating flow baseline should prompt inspection of the circuit for trapped water.

Fig. 19.6 Pressure/volume loop from an infant on pressure-limited ventilation.

Loops

Pressure/volume and flow/volume are the commonest displayed loops. They are distorted by infant-ventilator interactions. If the screen is watched in real time, breaths that are relatively free from interaction can be identified when the infant is settled. Pressure/volume loops can be inspected to determine the critical opening pressure of the airspaces and the upper inflection point where the slope of the pressure/volume relationship begins to flatten because of overdistension. This has been used in adults to facilitate less damaging ventilation strategies (Ranieri et al. 1999). However, in order to plot the progressive change in lung volume that occurs for a given change in pressure, the pressure has to rise slowly enough to allow changes in volume to keep pace. Pressure-limited neonatal ventilators generate relatively square pressure waves with a rapid rise to peak inspiratory pressure and an equally rapid fall to the PEEP level in expiration. This means that the changes in lung volume during inspiration are mostly plotted against the peak inspiratory pressure and during expiration against the end pressure, giving the loops a rectangular appearance which bears little relationship to the underlying pressure/volume characteristics of the lung (Fig. 19.6). Significant leaks around the endotracheal tube make interpretation even more difficult.

Inspection of flow/volume loops can give information about airway resistance. If resistance is increased, flow is slower. This can be observed from the time-based waveforms without the need to look at flow/volume loops. If there are secretions in the endotracheal tube, the expiratory limb of the loop can show a saw-tooth

pattern, indicating the need for endotracheal suction (Jubran and Tobin 1994).

Neurological system monitoring

Compared with the respiratory and cardiovascular systems, there is little available for continuous neurological monitoring. Examination of the nervous system is often intermittent and assessment subjective. It is more difficult when sedative drugs and neuromuscular paralysis agents are given.

EEG, aEEG and cerebral function monitors

Continuous electroencephalography (EEG) recording is now feasible and clinically useful. EEG is the best method for detecting seizure activity. Changes in the background give important prognostic information following hypoxic–ischaemic injury (Ch. 40.4).

Interpretation of the full EEG can be difficult and techniques to simplify the data have been introduced. Amplitude-integrated EEG (aEEG) monitoring is a compressed and rectified signal from one or more channels of EEG. The original ‘cerebral function’ monitors produced only one channel of aEEG with no access to the raw signal, but digital technology now allows multiple channels with access to the underlying EEG signal, which helps with artefact rejection. The aEEG has been shown to be helpful in monitoring cerebroelectrical background activity in sick neonates and in detection of subclinical seizures (Toet et al. 2008). It has a predictive value in the first hours of life following asphyxial injury (Spitzmuller et al. 2007). The interpretation of the aEEG trace, and its prognostic value, in babies undergoing therapeutic hypothermia still needs further evaluation. There are some preliminary data to show that cooling delays return of sleep–wake cycling in babies who will have a good outcome (Thoresen et al 2010). Its use in the preterm baby has been less clearly defined although reference values have been published (Olishar et al. 2004) and there are some data on its use in predicting outcome in preterm infants with large intraventricular haemorrhages (Hellstrom-Westas et al. 2001).

Although aEEG can be used for long periods, it must be remembered that it is a simplified method for monitoring electrocortical background activity and has limitations. Its simplicity is an advantage but can result in difficulties in interpreting whether a pattern represents seizure or other activity. At least one standard EEG should be recorded in monitored infants.

Cerebral ultrasound

Ultrasound offers an easy method of imaging the neonatal brain. Repeated scans allow progress to be monitored and give

prognostic information. Abnormalities that persist are more likely to be genuine, and most conditions evolve over time, allowing more certain diagnosis. Ultrasound changes must be interpreted with care.

Intracranial pressure monitoring

Indirect measurements of intracranial pressure taken across the anterior fontanelle have been found to be unreliable and inaccurate. Invasive intracranial pressure monitoring may have its place in specialist units, but has not been shown to improve outcome in the baby with neonatal encephalopathy secondary to a hypoxic–ischaemic insult.

Near-infrared spectroscopy

NIRS is capable of providing information on cerebral haemoglobin oxygen saturation, cerebral blood volume, cerebral blood flow, cerebral oxygen delivery, cerebral venous saturation and cerebral oxygen availability/utilisation. Compared with aEEG, NIRS as a monitoring device is less well integrated in neonatal intensive care but this is changing. Particularly in cardiac surgery cerebral monitoring, together with aEEG, is becoming more commonly used not only during cardiopulmonary bypass but also before and in the hours and days after surgery (Toet and Lemmers 2009).

Temperature monitoring

Measuring central temperature is important. The rectum should not be used as there is a small risk of damage to the mucosa. Rectal temperature is unreliable and is affected by the depth of insertion of the thermometer, whether the baby has just passed a stool and by the temperature of the blood returning from the lower limbs.

The temperature of the skin over the liver or in the axilla reflects central temperature. A more accurate measurement can be obtained by placing the probe between the scapulae and a non-conducting mattress. No tape is needed on the skin since the baby lies on the probe, holding it in place. This so-called zero heat flux temperature has been shown to be very close to the central temperature (Dollberg et al. 1993).

The measure of a single temperature tells us how well the baby is maintaining that temperature but nothing about how much energy is being used to achieve thermal balance. The continuous measurement and display of a central (abdominal, axillary or zero heat flux) and a peripheral (foot) temperature detects cold stress. Figure 19.7 shows an increasing temperature gap during a procedure. The baby is exposed to cold stress, but if the central temperature alone was being measured, then this would not have been apparent. Central measures of temperature vary, but the baby is

Fig. 19.7 Trend in central (top trace) and peripheral (bottom trace) temperatures, showing widening of the gap during handling, with slow recovery after the procedure.

usually between 36.8°C and 37.3°C with a central–peripheral temperature gap of around 1°C.

A high central temperature, particularly if unstable, along with a wide central–peripheral gap is seen in septic babies (Messaritakis et al. 1990).

Monitoring the sick baby

What needs to be monitored will always depend on the clinical condition of the baby. Invasive devices carry risks but continuous intra-arterial BP monitoring is important in the sick or unstable baby, including the ventilated preterm newborn. Continuous measurement and display of a central and a peripheral (foot) temperature give important information on thermal balance as well as some indication of tissue perfusion.

Monitoring oxygen, carbon dioxide and acid–base state is essential in intensive care. There must be a method of continuous oxygen monitoring, although there will still be a need for intermittent blood sampling. This is usually done every 4–6 hours but may need to be more frequent if there are repeated changes in ventilation or the clinical condition fluctuates. All ventilators must display online respiratory function parameters as well as waveforms and loops. Close monitoring of tidal volume is important in preventing lung overdistension.

Although continuous oxygen monitoring is considered a standard of care for the sick neonate with lung disease there has been a failure to show its effect on clinically meaningful outcomes. Despite the lack of comparative literature, saturation is now the most widely used method but this is subject to artefact and can underestimate both hypoxia and hyperoxia.

The use of oxygen has been closely linked to retinopathy of prematurity (ROP) and brain damage (Tin et al. 2001). There is evidence that fluctuations in oxygen levels within the baby may be important in the pathogenesis of ROP (Cunningham et al. 1995) and the use of saturation monitors has been associated with significantly more variable oxygenation than with transcutaneous monitors (Quine and Stenson 2008).

Before deciding on the best technique for oxygen monitoring we need more data on how to prevent ROP and other oxygen-related disorders. We need to know the relative importance of the absolute level of oxygen and the degree of fluctuation in P_{O_2} before we can decide on the optimum method of continuous monitoring (Poets and Bassler 2008). There is a conflict between trying to reduce mortality while preventing conditions such as severe retinopathy (SUPPORT study group 2010). Further randomised trials (BOOST-II) are underway to try and help answer the question as to the best baseline level for saturation in the preterm baby but fluctuations in oxygen may be equally important.

At this time the upper limit for a preterm baby receiving oxygen should be set at 95% to try and avoid significant periods of hyperoxia. Setting tight limits will result in very frequent alarms. Using an alarm range of 86–95%, while aiming to keep the baby around 90%, is reasonable but this recommendation may well change once the current trials are complete. If the preterm baby is breathing air then it may be reasonable to set the upper alarm to 100% but it is important to lower this again if oxygen is given.

There is less anxiety about the upper level of oxygen saturation in the term baby and this should be set at 98% with a lower limit of 92%.

In babies with persistent pulmonary hypertension the upper limit should be set to 100%. The lower limit may have to be lowered if there are frequent alarms due to the condition of the baby. This must be an individual clinical decision.

These limits may be unsuitable for babies with cyanotic heart disease; in this group levels need to be decided clinically for each baby and are often around 75–85%.

Clinical and laboratory monitoring

Infection

Infection is an important cause of morbidity and mortality. Babies must be screened whenever there is a clinical indication of suspected sepsis. The screen should include culture of blood, cerebrospinal fluid, urine, secretions and swabs, although which are needed in each case will depend on the clinical picture and policy of the individual unit.

The coagulase-negative *Staphylococcus* is commonly grown in cultures and the differentiation of infection from colonisation can be difficult. In all situations the result of cultures must be interpreted in the light of the clinical features and other supportive laboratory tests, particularly differential white count, platelet count and C-reactive protein. There are many studies looking at the best predictors of infection in the neonate but none have come up with any method that has acceptable values for sensitivity and specificity.

In the ventilated baby there is debate about the usefulness of routine culture of endotracheal aspirates. These cultures have a very poor predictive value (Lau and Hey 1991) and have not been found to be predictive of pathogens that are subsequently isolated during an infective episode (Slagel et al. 1989). The organisms isolated usually reflect colonisation and this practice can lead to overdiagnosis and antibiotic overuse with the risk of increased resistance developing. Many false negatives may also lead to undertreatment. There is a need for a robust definition of ventilator-associated pneumonia in the newborn which will allow better surveillance and targeting of infections associated with this invasive therapy. Until this time the routine cultures of tracheal aspirates offer little of diagnostic value.

Fluid balance (see Ch. 18)

Input/output charts should be used to help assess fluid balance, but it is important to measure all fluids given to the baby, including drugs and flushes for catheters (Noble-Jamieson et al. 1986).

Allowance must be made for evaporative fluid losses unless the baby is nursed in high humidity. Respiratory fluid losses can be high if there is inadequate humidification of the ventilator gases.

Urine output can be assessed by using pre-weighed nappies or cotton wool balls, but these must be weighed as soon as possible after voiding, to avoid evaporative loss (Cooke et al. 1989).

Fluid shifts in the baby are reflected in weight changes, but it is difficult in clinical practice to get good reproducible measurements, even when using within-incubator scales.

In the first days of life, changes in plasma sodium reflect hydration, with hyponatraemia being due to fluid overload and hypernatraemia to dehydration. Analysers now measure sodium along with the blood gases. Several measurements of plasma sodium throughout the day, along with the input/output and weight chart, give a good estimate of fluid balance in the sick neonate.

Biochemistry

As well as repeated estimations of plasma sodium, to help assess fluid balance, other electrolytes, glucose, creatinine, bilirubin and calcium should be measured once daily, and more often if clinically indicated. Laboratory methods are discussed in Chapter 42 and

normal values are given in Appendix 6. If parenteral nutrition is being used, then appropriate biochemical monitoring is essential (Ch. 17).

Haematology

Blood losses from sampling should be recorded and the sick ventilated baby must have a haemoglobin and/or haematocrit measured at least daily. Deciding on the optimum time for transfusion with red cells is difficult and there are no good data in the literature to help. Individual units need to develop their own guidelines.

Thrombocytopenia is often seen in sepsis, particularly if there is a consumptive coagulopathy or where central intravenous lines have been infected with coagulase-negative staphylococci. In ill babies, the platelet count, clotting studies and fibrinogen should be monitored regularly. Heparin in arterial lines can contaminate the samples for clotting studies and care must be taken in the interpretation of the results.

Daily total white counts, and the differential, can give an indication of developing sepsis. Absolute values are very varied, but changes, either up or down, can be indicative of infection.

Flow charts and plotting results on graphs are useful as they show trends in biochemical and haematological data.

Point-of-care testing

Point-of-care (near-patient) testing is expanding with the development of highly accurate instruments.

Blood gas analysers on the nursery are a mandatory part of the equipment of any intensive care unit. Glucose should always be measured using whole blood glucose analysers such as the Yellow Springs, although most blood gas analysers will also measure blood glucose. Cotside stick methods (Dextrostix, BM-glycaemie, or Reflostix) are no longer considered sufficiently accurate for neonatal use (Ch. 34.1).

New generations of analysers allow the measurement of a whole range of parameters without sending blood to the laboratory. Each unit must determine which bedside tests are indicated based on an analysis of test accuracy, clinical importance and cost-benefit ratio. There are major issues about maintenance of appropriate standards and quality control that also need to be addressed.

X-ray monitoring (Chs 43 and 44)

Although routine radiographs have been shown to be safe and not expose the extremely-low-birthweight infant to any excessive radiation risk (Sutton et al. 1998), the use of X-rays should be limited and determined by clinical need.

The chest X-ray is vital in the initial assessment of all babies with respiratory disease. Further X-rays, throughout the course of the respiratory illness, should be done as clinically indicated.

Abdominal X-rays help in the diagnosis of necrotising enterocolitis (NEC) and in detecting intestinal perforation. There is debate as to how often these X-rays should be repeated in infants with NEC, but in a very sick baby X-rays are indicated at least daily (sometimes more often) because perforation can be difficult to detect clinically.

There are many other indications for X-rays, including checking the position of endotracheal tubes and the tips of central arterial and venous lines.

Intravenous pumps

All pumps used to deliver intravenous fluids must have in-line pressure alarms. These detect occlusion in the line distal to the pump.

Many have adjustable limits and can be set to detect small changes in pressure, which could give an early warning of fluid extravasation into the tissues.

Unfortunately there is no evidence that any of the currently marketed infusion devices are capable of predicting or detecting infiltration in any patient population. Pressure changes caused by patient movement are far greater than those found in the early stages of fluid extravasation (Phelps et al. 1990).

Close observation of the infusion site at regular intervals, stopping the infusion at the first sign of swelling or redness, is all that is available to detect fluid extravasation and hopefully prevent or minimise subsequent tissue damage. Scarring from tissue infiltration is now a common cause of complaint and litigation. It is important that all units have a policy for the observation of intravenous infusions and that there is a record of the sites being observed at least hourly.

Data handling

Technical advances have increased the amount and complexity of data from monitors, but more is not necessarily better. For example, although there are theoretical reasons why the large number of parameters available from ventilator monitors should be helpful, there is, for many, little evidence that in routine clinical care they make any difference. Inexperienced doctors and nurses, who may be responsible for much of the day-to-day care, are faced with increasingly complex, and potentially useless, information, before they have even grasped the basic principles. There is a serious danger of data overload. An increasing multitude of alarms, often indicating minor technical problems only, result in the 'crying wolf' situation, with staff less likely to react appropriately to correct alarms (Tsien and Facklet 1997). There is a need to assess critically what is essential for the care of the baby, and the introduction of new monitoring parameters should be resisted without assessment of their usefulness by rigorous clinical trials.

Monitoring is not just about reading values from machines. It is the ability to integrate a whole range of data, including observation of the whole baby, into meaningful information. 'Experience' and 'gut feeling' are really recognition of patterns, although the process may occur subconsciously. Experienced nursing staff are an essential part of the monitoring of the baby and they often raise concerns about potential problems. However, even the most experienced clinical staff can be slow at recognising developing problems even when the patterns, on retrospective review, have been obvious for some time (Alberdi et al. 2001).

Continuous trend monitoring

Monitors and blood tests give information on the condition of the baby at a single moment. Displaying data as a continuous graph allows trends to be visualised, hopefully facilitating detection of abnormalities and allowing earlier intervention. The typical patterns in the trends of central-peripheral temperature differences shown in Figure 19.7 are a good example.

Plotted trends can show that a parameter is changing significantly, even before the values are outside the set alarm ranges. They may also make it clearer which readings are due to artefact.

Figure 19.2 shows the high P_{CO_2} associated with a blocked endotracheal tube, necessitating an emergency reintubation. Although the clinical deterioration was sudden, it can be seen that the P_{CO_2} had been rising slowly for several hours. Earlier assessment may well have avoided the subsequent collapse. Trend monitoring of T_{CO_2} may also facilitate earlier diagnosis of pulmonary air leak (McIntosh et al. 2000).

A randomised controlled trial of trend monitoring in neonatal intensive care failed to show that it improved outcome (Cunningham et al. 1998). Data overload, an inability to ascertain which data were important, a failure to include enough relevant information, or simply that staff were ignorant of the patterns that existed may be the reasons why trend monitoring did not make any difference to outcome. Also, it is often the change in a number of

parameters that is important and it can be difficult to visualise these all at once. Computers can be used to recognise complex trends and what is needed are computerised decision support systems if the full potential of continuous trend data is to be recognised (Alberdi et al. 2000). In such systems, artefact detection and removal remain a challenge, but this has been shown to be feasible (Cunningham et al. 1994b).

Dehydration fever	372
Gastroenterological symptoms	372

Healthy term newborn babies are most appropriately cared for by their mothers, supervised by midwives. The National Institute for Health and Clinical Excellence (NICE) has produced two documents, *Intrapartum Care* (2007) and *Postnatal Care* (2006), which contain helpful advice (see Weblinks, below). Clear protocols and guidelines are needed to manage the baby who develops a problem such as symptomatic hypoglycaemia, jaundice, sepsis or hypernatraemic dehydration. Minor problems are common and often cause considerable parental anxiety, but they are rarely of clinical importance.

The information in this chapter aims to guide those who are responsible for well term newborns, highlighting common problems and areas where local protocols need to be developed. The normal newborn examination is detailed in [Chapter 14](#).

Anticipatory care

Most maternal illnesses have no serious effects on the baby ([Ch. 11](#) and [Table 20.1](#)). Nevertheless, awareness of such illnesses is essential so that appropriate and prompt action can be taken to prevent unnecessary sequelae, such as severe jaundice in babies with a family history of hereditary spherocytosis. Fetal medicine has had a dramatic impact in this area, often providing prior warning of diverse problems such as ambiguous genitalia, cardiac disease and intrathoracic masses ([Ch. 9](#)).

Table 20.1 Maternal illness: effect on the baby and neonatal management

MATERNAL ILLNESS	EFFECT ON BABY	NEONATAL MANAGEMENT
Cardiovascular disease		
Ischaemic heart disease	–	–
Rheumatic heart disease	–	–
Congenital heart disease		
Acyanotic	Increased risk of congenital heart disease	Echocardiogram
Cyanotic	IUGR Increased risk of congenital heart disease	Echocardiogram
Hypertension	IUGR, may need to be delivered preterm Neonatal hypotension from drug therapy; hypoglycaemia from labetalol	Check blood pressure if unwell Check glucose in babies whose mothers were given labetalol (Ch. 34.1)
Respiratory disease		
Asthma	IUGR if severe Increased incidence of asthma	No neonatal intervention proven to reduce the risk of asthma
Chronic bronchitis	IUGR	–
Cystic fibrosis	–	No hazard from maternal lung pathogens. Breastfeeding is safe
Endocrine and metabolic disease		
Diabetes*	Infant of a diabetic mother (Ch. 22)	Needs careful neonatal evaluation
Thyrotoxicosis*	Neonatal thyrotoxicosis (Ch. 34.2)	Needs careful neonatal evaluation
Hyperparathyroidism	Neonatal hypocalcaemia (Ch. 34.2)	Monitor serum calcium during first 7 days
Other endocrine disease, e.g. Addison disease, hypothyroidism	–	–
Phenylketonuria*	Impaired development and microcephaly. Congenital heart disease	Nothing can be done in the neonatal period
Gastrointestinal disease		
Coeliac disease	–	–
Crohn disease	Prematurity or IUGR if severe	–
Ulcerative colitis	Prematurity or IUGR if severe	–
Peptic ulceration	–	–
Stomas, colostomy	–	–
Renal disease		
Chronic renal disease (nephrotic, renal failure)	IUGR Some forms of renal disease are hereditary, e.g. polycystic disease, Alport syndrome	Depends on aetiology and inheritance risk
Urinary infection	IUGR	Usually none Investigate if mother has vesicoureteric reflux
Neurological disease		
Epilepsy: effect of anticonvulsants	Teratogenic drug effects, but rare with common anticonvulsants Sedation from maternal drugs Occasional withdrawal symptoms Sedation from maternal drugs in breast milk (rare)	Extra maternal vitamin K no longer recommended Monitor Monitor Monitor, breastfeeding rarely interrupted

Table 20.1 Continued

MATERNAL ILLNESS	EFFECT ON BABY	NEONATAL MANAGEMENT
Dystrophia myotonica*	Infant affected (usually more severely) May be seriously ill in respiratory failure	See Ch. 40.7
Myasthenia*	Neonatal myasthenia (Ch. 40.7)	Monitor, usually no problems
Degenerative disease	–	–
Multiple sclerosis	–	–
Motor neurone disease	–	–
Infection in the mother		
Pyrexia of unknown origin	–	Monitor for infection
Recognisable acute infection	Usually nil Risk greatest for viral infections (Ch. 39.2)	See Ch. 39.2
Chronic maternal infection and carrier state*	Can be serious, e.g. human immunodeficiency virus, tuberculosis	See Chs. 11, 39.2
Allergic disorders		
Hayfever, eczema	Inherited atopic tendency	Avoid early allergen exposure (e.g. cow's milk), particularly if mother has severe atopic disease
Haematological disorders		
Anaemia (iron, folate deficiency)	–	–
Autoimmune haemolytic anaemia	IgG transmitted to fetus causing haemolysis	Monitor for jaundice and anaemia
Haemoglobinopathies	Neonatal problems uncommon since most are β -chain defects (Ch. 30)	–
Hereditary spherocytosis	Neonatal haemolysis and jaundice in the 50% of infants affected	Monitor for jaundice and anaemia
Idiopathic thrombocytopenic purpura	Fetal haemorrhage can occur but is rare Neonatal haemorrhage also rare	Check platelet count and observe for bleeding. May need treating (Ch. 30)
Glucose-6-phosphate dehydrogenase deficiency	Neonatal jaundice Increased risk of infection (Ch. 29.1)	Monitor for jaundice and sepsis
Inherited thrombophilic disorders (e.g. factor V Leiden)	Increased risk of stroke or CSVT (Ch. 40.3) in baby, if also affected	
Autoimmune disease		
Systemic lupus erythematosus*	Congenital heart block	Cardiac pacing if heart block (Ch. 28). No treatment if heart rate normal
Psychiatric disorders		
Bipolar disorders	Lithium treatment associated with congenital heart disease, arrhythmias	Balance risk of treatment according to maternal mental state; consider withdrawing lithium in first trimester and 7–10 days before term
Drug dependency	IUGR Drug withdrawal Drug effects (occasionally)	Monitor and treat drug withdrawal (Ch. 26)

Table 20.1 Continued

MATERNAL ILLNESS	EFFECT ON BABY	NEONATAL MANAGEMENT
Malignant disease		
Ongoing malignancy	May need preterm delivery	–
Previously treated malignancy	Reduced fertility but no neonatal effects except IUGR after Wilms' tumour	–
Miscellaneous		
Abdominal trauma	Rare	–
Malnutrition	IUGR (Ch. 10)	–
Smoking	IUGR Increased respiratory morbidity and sudden infant death syndrome in infancy	–
*Maternal illnesses that may seriously affect the baby. CSVT, cerebral sinus venous thrombosis; IUGR, intrauterine growth restriction.		

Care immediately after birth

Neonatal resuscitation (Ch. 13.1)

Umbilical cord clamping

Umbilical blood flow decreases rapidly after delivery to less than 20% of the fetal value by 40–60 seconds of age (Gill et al. 1981). Physiological cord closure usually occurs within 3–5 minutes of birth but some cords pulsate for more than 15 minutes. There is no need to rush immediately to clamp the cord, since there are few risks associated with delayed clamping and there may be some benefits. Delayed clamping increases the risk of the neonate developing jaundice requiring treatment (McDonald and Middleton 2008). One randomised trial comparing time to cord clamping of 30 seconds versus 3 minutes showed benefit in haemoglobin levels both at 1 hour and 10 weeks in a group of 34–36-week gestation babies (Ultee et al. 2008). It is essential that there is a foolproof routine for clamping or ligating the umbilical cord, otherwise a fatal neonatal haemorrhage can ensue.

Umbilical cord care

Correct umbilical care during the first week significantly reduces the incidence of infection, not only in the neonate but also in the mother. Necrotic Wharton's jelly is readily colonised by organisms from the environment, which may spread to cause skin, conjunctival or systemic infection in the baby, or breast abscess in the mother.

Umbilical cord colonisation can be reduced by using topical antibiotics (Elias-Jones 1986). Yet, in developed countries, there is no evidence that topical antibiotics or antiseptics reduce systemic infection, and moreover they delay cord separation. Simply keeping the cord clean and dry is a reasonable and safe mode of care (Zupan and Garner 2000) and is the method adopted in the UK at present.

Prevention of eye infection

In many countries, it was routine to administer one drop of 0.5–1.0% silver nitrate into each eye immediately after delivery, to prevent gonococcal ophthalmia. Silver nitrate is effective, reduces

the incidence of other types of conjunctivitis and is largely free from side-effects (Bell et al. 1993), although babies find it uncomfortable and some studies have reported a chemical conjunctivitis in up to 90% of recipients (Nishida and Risenberg 1975). A 2.5% solution of povidone-iodine is more effective (Isenberg et al. 1995) and protects against chlamydial conjunctivitis, which is otherwise more difficult to prevent even with the use of erythromycin ointment. Whether or not prophylaxis is justified depends on the incidence and severity of neonatal conjunctivitis in the local population; it is not used in the UK. Many US states have now changed from silver nitrate to erythromycin.

Vitamin K

Haemorrhagic disease of the newborn is potentially fatal. It exists in an early and late form, and is primarily a risk in breastfed babies and those with liver disease (Ch. 29.2). The condition can be prevented by giving 1 mg of vitamin K intramuscularly (i.m.) after delivery to all babies (McNinch and Tripp 1991). A study that suggested an increased risk of leukaemia in later childhood generated considerable anxiety about the practice of universal i.m. vitamin K administration (Golding et al. 1992), but subsequent studies from different parts of the world – Sweden (Ekelund et al. 1993), the USA (Klebanoff et al. 1993), Denmark (Olsen et al. 1994), Germany (Von Kries et al. 1996) and the UK (Ansell et al. 1996) – have failed to confirm these findings.

Various oral regimens have been used, either to avoid giving injections or to avoid the putative risk of malignancy. From these studies it is clear that a single oral dose at birth does not eliminate the risk of haemorrhagic disease, particularly late-onset disease (Hanson and Ebbesen 1996), which in one series was 13 times more common after oral than after i.m. vitamin K prophylaxis (McNinch and Tripp 1991). Repeated doses of oral vitamin K have been suggested as an alternative to a single dose of i.m. vitamin K. Local practice in Britain varies, but the following are commonly used regimens. Konakion MM is the only licensed preparation currently available for prophylaxis against haemorrhagic disease of the newborn in the UK.

- i.m. Konakion MM – a single 1-mg dose at or soon after birth or

- oral Konakion MM Paediatric – 2 mg at birth and at 4–7 days for all babies, and a third dose at 1 month of age for exclusively breastfed babies.

Infants at increased risk of haemorrhagic disease because of maternal liver disease or maternal anticonvulsant or antituberculosis drugs, should receive i.m. or intravenous Konakion (Royal College of Paediatrics and Child Health 1999). In addition, there remains a concern that the oral regimen may not prevent late haemorrhagic disease, particularly in breastfed babies. This is only in part because of the failure to administer a complete course (Von Kries et al. 1995). This concern can be probably ameliorated by giving an oral dose of 2 mg at birth followed by 1 mg weekly for 3 months (Hanson and Ebbesen 1996; McNinch et al. 2007).

Thermal care (Ch. 15)

The normal axillary temperature is 36.5–37.5°C (Chs. 15, 19).

The risk of developing hypothermia is greatest immediately after delivery. It is not uncommon for the body temperature of a normal full-term baby to drop to 35–35.5°C by 15–30 minutes of age. The adverse effects of hypothermia are detailed in Chapter 15 and include hypoglycaemia, acidosis, pulmonary hypertension and impaired surfactant production.

In order to prevent hypothermia the underlying mechanisms of heat exchange, namely evaporation, conduction, convection and radiation, must be considered (Ch. 15). Evaporative heat loss, even from babies born into a water pool, is almost eliminated by prompt drying. Conductive heat loss is lessened by prewarming the towels and any other equipment that will be in contact with the baby. Convective heat loss is ameliorated by having a warm and draught-free delivery room and covering the baby. All doors and windows should be closed, air circulation systems likely to cool the baby should be turned off (or the baby placed away from the air vent) and the room temperature should be at least 20°C. Radiant heat is lost from the exposed skin of the baby to any surrounding surfaces that directly overlook the infant, and is proportional to the difference in temperature between these surfaces and to the distance between the surfaces. This problem is readily overcome by avoiding leaving the baby exposed and staying away from cold (external) windows and walls. Radiant heaters and heated blankets achieve a reversal of some of these processes and can allow the infant to gain heat.

Many mothers wish to have early skin-to-skin contact with their baby and this should be encouraged. Because the baby will be naked, it is sensible to increase the temperature of the room to a level comfortable for a naked and resting person (23–25°C) and/or use an overhead heat source. The baby should be dry and covered with a warm towel or sheet, and draughts should be excluded. These are all wise precautions that do not distract from an intensely personal experience. Babies cared for like this maintain their body temperature, cry less, have better blood glucose control and base-excess values than do cot-nursed babies (Christensson et al. 1992). They are also more likely to establish successful long-term breastfeeding (Righard and Alade 1990).

Bathing babies shortly after birth may cause neonatal hypothermia and should be avoided. Most blood, meconium and vernix is quickly and effectively removed during the initial drying in warm towels, and thereafter any surplus can be wiped clear with a tissue.

Measurement

Babies should be weighed shortly after birth. The head circumference should also be recorded at this stage.

Labelling and security

In hospital, as opposed to home confinements, it is essential to attach a nametag immediately after delivery to prevent incidents of confused identity. There seems to be little benefit, however, from the more complex procedure of footprinting the baby (Thompson et al. 1981).

Bonding

Developmental care is outlined in detail in Chapter 4. In simple practical terms, both parents should be left alone with their baby immediately after birth, when babies are particularly bright-eyed and attractive. Putting the baby to the breast early is one of the most important determinants of successful lactation (Christensson et al. 1992) and, by releasing oxytocin, promotes uterine contraction, the milk ejection reflex, and complex maternal behavioural responses (Unvas-Moberg and Eriksson 1996). Moreover, simple skin contact at this stage has been shown to stimulate release of maternal oxytocin and prolactin and aid the first breastfeed (Righard and Alade 1990).

The normal neonate

Cardiorespiratory function

The normal term infant has a pulse rate of 110–150 beats/min and a blood pressure of 50–55/30 to 80/50 mmHg (Appendix 4). Occasional ectopic beats are quite common. The respiratory rate should be less than 60 breaths/min and is usually 35–45 breaths/min. Periodic breathing, with bursts of respiratory activity separated by apnoeic pauses of 3–10 seconds, is normal in preterm babies but is rare at term (Ch. 27.4).

Temperature

The term baby maintains a core temperature very close to 37°C, so that any departure from this always requires careful evaluation, in particular to exclude sepsis. For the healthy clothed term baby who is in a cot, keeping the room temperature at 20–22°C is adequate. If the room temperature falls below 20°C, the baby should be covered with a blanket and may need to wear a bonnet. It is very important, however, to avoid overheating by lying the baby by a radiator, in direct sunlight, overwrapping or putting an external heat source inside the cot.

Weight changes

All babies should be weighed shortly after birth. Normal infants lose up to 10% of birthweight by the fifth day, primarily as a result of extracellular water loss. Only 3% of the babies in the Millennium Baby Study failed to regain their birth weight by the 12th day (Wright and Parkinson 2004). Most babies who are discharged early are currently not weighed again, but a re-evaluation of the practice has recently been suggested, and seems sensible (Laing and Wong 2002).

Weight loss in the first few days averages 4–7% and should not exceed 10% of the birthweight. Weight loss should always be assessed in relative terms, even though it means that a 4500-g baby may lose up to 450 g. In general, breastfed babies lose more weight (5–10%) than bottle-fed ones (2–6%) (Maisels et al. 1988), but this difference may be less if the baby breastfeeds more frequently (Avoa and Fischer 1990). From 1 week of age, the normal baby should gain weight at about 10–15 g/kg/day until the age of 6 months.

Urine output and staining of nappies

Many babies pass urine immediately after birth, and then, particularly if breastfed, may pass very little urine in the next 24–36 hours. It is very unusual for any illness to present in an otherwise normal baby solely with anuria or oliguria. Normal neonatal urine is virtually colourless. Pink staining of the nappy is commonly due to harmless urate crystals.

Bowel activity

Many babies open their bowels in the first few minutes, and usually regularly thereafter. There was no difference in the time to first stool (7–8 hours) between breast- and formula-fed babies in one study of 1000 babies in Buffalo, and 99.7% had passed at least one stool

by 36 hours (Metaj et al. 2003) (Fig. 20.1). Initially babies pass meconium, a dark-greenish substance composed of intestinal secretions, bile, swallowed amniotic debris and the remains of desquamated intestinal mucosal cells. By 2–3 days, 'changing' stools, a mixture of meconium and more normal stools, are passed. Once feeding is established, breastfed babies pass very soft mustard-yellow stools, often with every feed. Their stools are acid (Kleessem et al. 1995). Bottle-fed babies pass a less acid, firmer and paler stool, only once or twice a day.

Neurological activity

The neurological capabilities of the neonate are outlined on Ch. 40.1. Newborn babies can see, and prefer a face to 'scrambled'

Fig. 20.1 Time to first stool (A) and urine (B) in 1000 healthy babies of >34 weeks' gestation; 99% had passed their first stool and first urine by 34 hours' postnatal age. (Redrawn from Metaj et al. (2003).)

shapes, they can hear and smell, and within the first few days and weeks of life they learn to recognise their mother by these senses (Trevarthen *et al.* 1981; Varendi *et al.* 1994).

In the neonatal period, babies have irregular sleep–waking cycles. In the first few days they spend up to 18 hours asleep, with 50–60% of the sleep being rapid-eye movement (Schulte 1981). They wake to feed or when uncomfortable, usually because the nappy is wet or soiled, but the sleep–wake pattern gradually becomes more regular. Circadian rhythmicity in heart rate and body temperature is detectable by 1 month of age (Glotzbach *et al.* 1994).

Postnatal care

Routine observation

At about 4 hours after birth, it is desirable to make a check of general well-being and to measure the baby's temperature, pulse and respiration. In hospital, this is often conveniently done on admission to the postnatal ward. In this situation, the baby's identity should also be verified, the security of the cord clamp confirmed and a check made to ensure that vitamin K has been given. There is no need routinely to check the blood pressure, haematocrit or blood glucose (American Academy of Pediatrics 1993). Thereafter, temperature, pulse and respiration should be recorded if the baby becomes unwell. Temperature instability, tachycardia and tachypnoea are important signs of neonatal sepsis (Ch. 39.2; Mifsud *et al.* 1988). Feed charts have largely been abandoned, but an observation chart should be used when appropriate (for example, see Fig. 21.1).

Rooming-in

Standard management should be that the mother and her baby remain together all the time. This helps to prevent cross-infection and promote successful breastfeeding. It also facilitates the mother's desire to learn how to recognise, respond and manage every demand and need of her baby. If the mother is ill or exhausted, or if she requests it, help may be needed to settle her baby.

Sleeping position

The risk of sudden infant death syndrome (SIDS) is reduced if babies are placed to lie on their back (Oyen *et al.* 1997). Side-sleeping is less safe and sleeping on the front is associated with the highest risk (Mitchell *et al.* 1997). Occasionally, babies are placed to sleep on their front for medical reasons, but this is the exception. The risk of SIDS is also reduced by the avoidance of cigarette smoking during pregnancy, avoiding exposure of the baby to cigarette smoking after birth, and by precautions to avoid overheating.

Prevention of infection on a postnatal ward

Handwashing

The major risk to the normal baby is from organisms carried by medical and nursing staff, who must be meticulous in washing their hands before they touch any baby. The extended family should do the same. The parents (particularly the mother) and baby quickly share commensal organisms, but, even so, good hygiene is important. Gowns are not required for staff or family (Birenbaum *et al.* 1990).

Baby washing

If the cross-infection techniques are good, and the baby rooms in, so that he is colonised from the mother, all that is required is a wash with baby soap. If there is an outbreak of skin infection, then chlorhexidine washing can be instituted. The use of hexachlorophene to wash babies should be avoided because it can be toxic (Martin-Bouyer *et al.* 1982).

Visitors

Healthy visitors are not generally an infectious hazard, and the number allowed should be decided on a common-sense basis. There are rarely justifiable medical reasons why fathers, siblings and grandparents should not be allowed free access to the new family member. The exception to this has been the recent swine flu epidemic; young children are 'super-shedders' of flu virus and many maternity hospitals have justifiably excluded them from visiting on these grounds.

Cord care

The early care of the cord with simple cleaning is described above. A 'healthy' cord is dry. The cord usually drops off naturally within 2 weeks, but this may be delayed if antibiotics or antiseptics are applied (Zupan and Garner 2000).

Well-baby care

The hazards of hypothermia lessen once the baby has adapted to extrauterine life, and so it is not necessary to delay washing beyond the second or third day of life. At this time the mother can participate fully. This first wash can be just 'topping and tailing', that is, washing the face and hair and cleaning up the groin and perineum. For inexperienced mothers, this first bath may need to be supervised or even demonstrated.

The foreskin

At birth the foreskin is adherent to the surface of the glans penis, and is not meant to be retractile. Indeed, the foreskin remains non-retractile in most boys until about 2 years of age. Forcible retraction during infancy tears the prepuce and may cause later scarring and phimosis. There is some evidence that urinary infections are less common in circumcised boys (Schoen 1993; Craig *et al.* 1996), but this is not sufficient justification for routine neonatal circumcision (Winberg *et al.* 1989). Parents who elect to have their son circumcised usually do so for cultural or religious reasons. The operation should always be performed by a trained anaesthetic and surgical team.

Immunisations

Hepatitis B

In the UK, hepatitis B immunisation is offered to infants of mothers who are HBsAg-positive. Babies born to highly infectious mothers should also receive hepatitis B immunoglobulin. The first dose of the immunoglobulin should be given within 24 hours of birth, and ideally should be ordered in advance. Repeat doses of the active immunisation should be given at 1, 2 and 12 months of age. See the UK government 'Green Book' on immunisation for helpful advice (see Weblinks, below).

Tuberculosis (TB)

The recent rise in TB in the UK has led to a recommendation for universal TB vaccination in many inner-city areas. The 'Green Book' recommendation is for vaccination of infants living in areas of the UK where the annual incidence of TB is 40/100 000 or greater, or with a parent or grandparent who was born in a country with such an incidence (see Weblinks, below).

Routine neonatal clinical examination (Ch. 14)

Timing and personnel

All newborn babies should be examined carefully at least once in the first few days. The examination should be carried out by an appropriately trained individual.

It is essential for those carrying out the examination to have a clear understanding of what they are trying to achieve. There are four main functions to the examination:

1. Detecting serious problems which would otherwise not have been detected and which merit early assessment and treatment. Basically there are only three common ones: congenital heart disease, developmental dysplasia of the hip, and eye defects.
2. Checking for many very rare but serious conditions, e.g. the enlarged bladder of posterior urethral valves, the posterior abdominal mass of a congenital tumour or a dermal sinus.
3. Noting and explaining to the parents the multitude of normal variations and minor anomalies that may be present (Table 20.2).
4. Health promotion: give advice on nutrition, reducing the risk of SIDS, parental smoking, transport in cars. It also gives the

parents a chance to ask about any aspects of the healthcare of their baby.

The examination has a low specificity and sensitivity, so findings must be interpreted with caution. On the one hand, the clinician has to be careful not to overinterpret signs found on the first day in such a way that the infant is subjected to unnecessary investigations and treatment, and the parents to unnecessary anxiety. On the other hand, most congenital heart disease is not detected at this examination and false reassurance should be avoided (Abu-Harb et al. 1994). The details of the examination are given in Chapters 14, 28.

Gestational age assessment

Gestational age is most accurately calculated using early antenatal ultrasound data and the menstrual history. Knowledge of whether a baby is preterm and/or small for dates may alter management, and so it is important to know such a baby's gestational age. Smaller babies may require more support in establishing sucking feeds and may take longer in making the transition to the extrauterine environment.

Biochemical screening

Currently in the UK, newborn screening is recommended for phenylketonuria (PKU), congenital hypothyroidism, cystic fibrosis (CF), sickle-cell disease and medium-chain acyl-CoA dehydrogenase deficiency (MCADD).

Phenylketonuria

At 5–9 days of age, all babies have a heelprick blood sample analysed for phenylalanine: a raised level may indicate PKU. The baby should only be tested for PKU if milk intake is normal. The blood is collected onto an absorbent card, taking care to fill each of the circles with blood. Approximately 1:2000 infants are positive on screening, about five times more than the prevalence of the disease (1:10 000). Those with positive tests are recalled and their plasma phenylalanine remeasured to determine whether or not they have PKU. If PKU or a variant is confirmed by a second raised phenylalanine level, the baby should be referred to a specialist centre for full investigation and ongoing care.

Congenital hypothyroidism

Using another of the blood spots, a radioimmunoassay is done for thyroid-stimulating hormone (TSH): those with a high TSH are then recalled for further evaluation. This is required in about 0.2–0.3% of all infants tested. The incidence of congenital hypothyroidism detected in this way is about 1:4000 (Ch. 34.2). All infants identified should be treated as quickly as possible.

Cystic fibrosis

The original blood spot screening test for CF was based upon the work by Crossley et al. (1979), which showed that immunoreactive trypsinogen (IRT) was significantly increased in neonates with CF (incidence 1:2000). The blood spot test as used at present first identifies samples with IRT values above the 99.5th percentile and subjects these to a two-stage mutation analysis for the CF transmembrane conductance regulator (CFTR) gene. Babies with CFTR mutations detected in both genes (either a homozygote or compound heterozygote) have a presumptive positive diagnosis of CF.

Table 20.2 Minor abnormalities and normal variations that may cause parental anxiety

Skin lesions
'Stork bite'
Milia
Erythema toxicum
Strawberry naevi (rarely present at birth)
Cutis marmorata
Miliaria
Mongolian patches
Innocent pigmented naevi
Epithelial pearls in the mouth
Cephalhaematoma
Subconjunctival haemorrhage
Peripheral and traumatic cyanosis
Tongue tie
Diastasis recti
Protuberant xiphisternum
Hydroceles
Sacral dimple
Umbilical anomalies, e.g. hernia
Physiological jaundice
Snuffles
Talipes calcaneovalgus
Vulval mucosal tag
Breast enlargement

Most babies with only one mutation detected will be unaffected carriers but there is a risk that they carry a second abnormal allele not detected by the mutation panel used. They are therefore tested again on a repeat dried blood spot specimen taken between day 21 and day 28 of life and assayed for IRT.

Sickle-cell disease

In areas of the UK where there are significant numbers of babies of ethnic groups known to be at high risk of sickle-cell disease (e.g. south-east London), neonatal screening is offered.

Medium-chain acyl-CoA dehydrogenase deficiency

About 1:10 000 babies born in the UK has MCADD. Screening allows most babies with MCADD to be recognised early so that dietary changes can be made to minimise the risk of serious illness.

Hearing screening

In the UK, 1–2:1000 babies are born with a hearing loss in one or both ears. Neonatal hearing screening is now offered to all newborn infants (<http://hearing.screening.nhs.uk/>).

Feeding the normal term baby

Human milk is undoubtedly the preferred food for term infants, and every effort should be made to encourage a mother to breast-feed. In the developing world, breastfeeding dramatically improves survival and so bottle-feeding should be avoided if at all possible. Schemes that give mothers accurate, evidence-based information about breastfeeding to enable informed choice of feeding method (such as the UNICEF Baby Friendly Initiative) demonstrate improvements in breastfeeding rates (Kramer et al. 2001; Tappin et al. 2001).

Breastfeeding

There have been numerous initiatives, through UNICEF, the Department of Health and the Royal College of Midwives. The 2005 Infant Feeding Survey (see Weblinks) showed that 78% of mothers initiate breastfeeding in England. Forty-eight per cent of all mothers in the UK were breastfeeding at 6 weeks, while 25% were still breastfeeding at 6 months. Between 2000 and 2005 there was a small increase in the prevalence of breastfeeding at all ages up to 9 months in England and Wales and Northern Ireland.

Preparation

Ideally, breastfeeding education should start in the antenatal period, with advice on what constitutes normal breastfeeding behaviour. Practical help should be available in the immediate postnatal period to assist in the proper initiation of lactation (Table 20.3).

Lactation

Following the expulsion of the placenta, the anterior pituitary gland releases large amounts of prolactin, a hormone essential for lactation. Frequent breastfeeds in the early postnatal period stimulate the development of prolactin receptors in the mammary gland. It is thought that breast milk output is related more to the number of prolactin receptors than to levels in the blood. Delayed suckling

Table 20.3 Policies to promote breastfeeding

Antenatal education
Baby put skin to skin soon after birth
Baby put to breast as soon after birth as possible
Establish rooming-in
Feed at least 8 times per day, up to 12 times if necessary
Do not have specific duration of feeds at the breast
Finish the first breast, going to the second if hungry
No supplementary/complementary feeds
No dummies
No discharge gift packs
Regular assessment of the mother's breasts

results in reduced levels of prolactin and thus fewer prolactin receptors stimulated. When the baby suckles, nerve impulses are sent from the breast to the posterior pituitary and oxytocin is released. Oxytocin causes the myoepithelial cells to contract and milk is squeezed from the alveoli towards the nipple and into the mouth of the suckling infant. This is the milk ejection reflex or let-down reflex. At first an unconditional reflex, it quickly becomes conditional and readily inhibited by anxiety and pain.

Initially, lactation is hormonally driven, and colostrum will be produced whether or not suckling takes place. Colostrum is thick, viscous and small in volume, with intakes of 4–14 ml each feed. Over the next 48–96 hours, milk production increases markedly and the volumes produced start to be governed by suckling and milk removal, activities that are essential for the continuation of lactation (Prentice et al. 1989). After 1–2 weeks, on average 700–800 ml/day of milk is produced, with a wide range from 450 to 1200 ml. At the end of each feed, about 100 ml of milk is left in the breasts (Dewey et al. 1991). Babies seem able to judge their own intake such that they grow normally, so an assessment of intake should only be attempted if weight gain is unsatisfactory.

Milk is produced for as long as it is removed from the breast. The rate of milk secretion may differ between breasts if the duration or frequency of suckling is not equal. This suggests autocrine regulation of milk secretion by the production of a local factor within each breast that controls lactation. This factor has been identified and is termed the feedback inhibitor of lactation (Wilde et al. 1995).

Attachment and positioning

Correct attachment and positioning are of fundamental importance to successful breastfeeding, so the mother should be taught these skills at the first feed. A helpful DVD is *From Bump to Breastfeeding*, produced by Best Beginnings (see Weblinks section). Correct technique ensures effective milk drainage and a satiated baby (Woolridge 1986), thereby minimising problems such as sore and cracked nipples, breast engorgement and mastitis. The baby will feed frequently until the milk supply is abundant. If incorrectly positioned, the stimulus for an increase in yield will be compromised and lactation will decrease. Resulting breast pain or anxiety about sufficiency of milk supply will inhibit the milk ejection reflex, a demoralising experience for the mother.

With the baby positioned for breastfeeding, the head and body must be in alignment, with the baby well supported in a position that is sustainable for mother and baby and brought in close to the mother's body. Correct attachment is vital for the lips to form a seal with the breast. The mouth is open wide against the breast and the tongue protrudes beyond the lower gum. The baby's nose is aimed

Fig. 20.2 Positioning for breastfeeding. The head and body must be in alignment, with baby well supported in a position that is sustainable for mother and baby and brought in close to the mother's body. The mouth is open wide against the breast and the tongue protrudes beyond the lower gum. The baby's nose is aimed toward the nipple to facilitate extension of the lower jaw. (Courtesy of Mother and Baby Picture Library/Ruth Jenkinson.)

Fig. 20.3 A correctly attached baby. (Courtesy of Mother and Baby Picture Library/Ruth Jenkinson.)

toward the nipple to facilitate extension of the lower jaw (Fig. 20.2). The baby is attached with the nipple adjacent to the junction of the hard and soft palate in the roof of the mouth. A significant amount of breast is drawn into the mouth, enabling the baby's jaw and tongue to compress and strip or milk the lactiferous sinuses. The nipple only forms one-third of the 'teat' in baby's mouth; the rest is breast tissue.

A correctly attached baby is shown in Figure 20.3. The baby's head is slightly extended and both nostrils are clear of the breast. The mouth is wide open and lips flanged backwards. The chin must be touching the breast. If the areola is visible, more should be seen above than below the mouth, indicating that the nipple is in the roof of the mouth. A correctly attached baby takes long deep sucks with pauses.

Frequency and duration

The optimum time to initiate breastfeeding is shortly after delivery, ideally during the period of skin contact, since for the first 2 hours

of life babies are usually alert and the sucking reflex intense. It is important not to miss this phase since thereafter babies enter a deep sleep before periods of wakefulness ensue, which are accompanied by the desire for frequent short feeds. Healthy infants may feed 10 or more times a day in the first few days and this should not be limited. At this time, when only colostrum is being produced, the baby should suckle both breasts during a feed. The duration of each feed is variable; in general, the endpoint is when the baby loses interest in sucking or the breast is empty, usually 7–10 minutes.

After the first few days, most breastfed babies will gradually settle into a 2–3-hourly feeding pattern. Most of the milk will come in the first 4–6 minutes, although many babies will continue to suck intermittently thereafter for comfort. At this time there is some evidence to show that prolonged feeding at one breast, ensuring that it is empty, reduces complications (Evans et al. 1995). Also, the fat content of breast milk increases during the feed, and so it is important not to limit the length of time a baby suckles (Woolridge and Fisher 1988). After this breast is empty, if the baby has gone to sleep, then the feed is over; however, if he is still hungry, some milk should be given from the other breast. To ensure that one breast at a time is completely emptied, the mother should alternate which breast she offers first.

Complementary and supplementary feeds

Complementary feeds are those offered after a baby has breastfed. Supplementary feeds are those that replace the entire breastfeed. They may be given from a bottle or cup. The additional feed of choice is mother's expressed milk. The decision to give additional feeds to a breastfeeding baby is a major one, since it frequently inhibits the establishment of successful breastfeeding (Kurini and Shiono 1991; Blomquist et al. 1994; Michaelsen et al. 1994). Probably the only genuine justifications for complementary or supplementary feeds are hypoglycaemia and dehydration with a weight loss more than 10–12% of birthweight. Whatever the reason for using complementary or supplementary feeds, the mother should, if at all possible, continue to express milk on a regular basis until breastfeeding is established. Topping up with water or a glucose solution is a major cause of lactation failure and should be avoided.

Monitoring breastfeeding

Whilst breastfeeding is being established, it is wise to monitor the frequency of feeds and the number of wet nappies, which should become heavier with urine. Weighing the baby should be done only when there is concern; if weight gain is poor or persistent weight loss occurs, examine the baby carefully for signs of ill health and take a urine sample to exclude infection. If there are no signs of illness, the problem is usually that of poor intake; in such babies, urine output is low and hypernatraemia is common.

Bottle-feeding

Starting feeds

Tables of composition of currently available formula milks compared with breast milk can be found in Chapter 16. The first feed should be offered at about 4 hours of age. Thereafter, the baby is fed on demand, which in most cases is about every 4 hours, less frequent than most breastfed babies. As with breastfed babies, there is no justification for offering water or a glucose solution.

Technique of feeding

The baby should be swaddled and held closely and comfortably to the mother so that she can hold the bottle with her free hand. Touching the baby's mouth or lips with the teat will usually evoke the rooting reflex. The mouth will open, the teat can be popped in, and he will begin to suck. The sucking mechanism is different from breastfeeding (Mathew 1991) since there is not the equivalent of the milk ejection reflex, so that, in addition to compressing the teat with the gums and squeezing milk into the mouth as in breastfeeding, the baby has to generate a vacuum in his or her mouth to suck the milk out of the bottle. The amount obtained per suck can be altered by varying the size of the hole in the teat, but, in general, large holes should be used only in babies with sucking problems.

Temperature

Traditionally, bottle milk is warmed to body temperature before feeding, but there is no need to do this. Babies take room temperature milk perfectly satisfactorily.

Frequency of feeds

Demand feeding should be the norm, and bottle-fed babies usually settle into a 3–4-hourly schedule, taking about six feeds per day.

Volume of feeds

Healthy term infants should be demand-fed and allowed to take what they want. Most babies who take the volumes outlined settle down to an intake of 150–180 ml/kg/24 h. As with breastfed babies, if weight gain is satisfactory, a relaxed attitude should be adopted towards individual variation.

Feeding problems

Feeding problems must be sorted out with the mother and baby together, and this may require readmission of both to the postnatal wards. Feeding problems are emphatically not an indication for transferring an otherwise normal baby to a neonatal unit.

Excellent advice on maternal problems can be found in the publication *Successful Breastfeeding*, third edition, Royal College of Midwives (2003).

Newborn feeding problems are common. Typical symptoms include poor feeding, crying, poor weight gain and vomiting.

Reluctant feeding

Babies feed at variable intervals and durations, and if a baby is gaining weight normally, he is getting enough nutrition regardless of his habit. The average number of feeds and wet and dirty nappies is six in 24 hours. The time to be concerned is if feeding lasts for only 2–3 minutes, if weight gain is poor or if a baby deviates from a previously established pattern of feeding. The first thing to do is to ensure that the baby has a normal oropharynx and is not ill. The examination should be focused on the detection of a cleft palate (clefts of the soft palate are unfortunately often missed by routine neonatal examinations), thrush or the rare occurrence of significant tongue tie. Also assess for signs of respiratory distress, congenital heart disease, infection, a dysmorphic syndrome (e.g. Down syndrome) or a primary neuromuscular disorder. Check for hypoglycaemia as a consequence (or even a cause) of a poor intake. Investigations will depend on the clinical circumstances.

If all these are normal but the baby still feeds poorly, the commonest causes are:

1. preterm
2. large for dates
3. the aftermath of a difficult delivery, e.g. vacuum extraction
4. sedation from intrapartum or antenatal drug therapy (e.g. maternal pethidine)
5. sedation from drugs in the breast milk (uncommon).

Prolonged sedation from drugs in breast milk is very unusual, and is rarely a contraindication to breastfeeding. If babies continue to be floppy and feed poorly, consider investigations along the lines suggested for hypotonia (Ch. 40.7).

Tongue tie (ankyloglossia)

Tongue tie is characterised by an abnormally short lingual frenulum. It varies in degree, from a mild form in which the tongue is bound only by a thin mucous membrane to a severe form in which the tongue is anchored to the floor of the mouth. Breastfeeding may be difficult because of an inability to suck effectively, causing sore nipples and poor weight gain.

Most tongue ties are asymptomatic and do not require treatment and others resolve spontaneously over time. If the condition is thought to be causing feeding problems, conservative treatment includes breastfeeding advice and massaging the frenulum. Some practitioners believe that if a baby with tongue tie has difficulty breastfeeding, surgical division of the lingual frenulum should be carried out as early as possible. However a systematic review by Suter and Bornstein (2009) suggests that at the moment there is no evidence for the best method of surgical management.

If division of the tongue tie is performed in early infancy, it is usually performed without anaesthesia, although local anaesthetic is sometimes used. The baby is swaddled and supported at the shoulders to stabilise the head and sharp, blunt-ended scissors are used to divide the lingual frenulum. There should be little or no blood loss and feeding may be resumed immediately. Many paediatricians are troubled by the use of surgical treatment without an anaesthetic.

Crying

Persistent crying in the neonate is usually due to hunger. There are many other causes for babies crying, notably pain. If the diagnosis is hunger, the appropriate treatment is milk, even if the baby was fed only 2 hours previously. If the crying baby shows no enthusiasm for feeding and is clean and dry, then he probably just needs a cuddle; skin contact can be particularly comforting. If this does not work, one must exclude occult but painful conditions such as otitis media, urinary tract infection, intussusception, bone and joint sepsis and incarcerated hernia. It is commonly believed that crying in a baby is due to wind, but this should be assumed only when other causes have been excluded. Infantile colic is discussed below.

Wind

The bottle-fed baby will usually swallow some air with a feed. This may be because the hole in the teat is too small to let milk into the mouth as quickly as a hungry baby wishes, and so he sucks air around the teat. A large hole may also result in air swallowing because the milk comes into the mouth too rapidly and the baby splutters. Poor parental feeding technique may allow the level of the milk in the teat to go below the hole in the teat, or the baby may continue to suck on an empty teat and swallow air. The

breastfed baby usually swallows less air during a feed. Air swallowing is most common in the first 2 weeks whilst supply and demand are being established. With insufficient milk, the baby may suck in air; with an abundance of milk, the baby may splutter at an over-vigorous milk ejection reflex.

Regardless of the type of feed, afterwards it is traditional to sit the baby upright in the hope that the stomach gas bubble will lie under the oesophageal hiatus and then, by rubbing or patting the back, the bubble will be induced to burst upwards – very satisfying for all. 'Winding' the baby in this way is supposed to prevent excess gas being propelled through the infant's small intestine, where, by analogy with older patients, it is believed to cause abdominal pain and/or infantile colic. This may not be evidence-based but it has a long tradition and appears harmless. Nevertheless, it should be considered the cause of crying only once an alternative explanation has been excluded.

Colic

Infantile colic can occur in the late neonatal period. Its aetiology remains a mystery, although food and lactose intolerance in the mother and baby have been investigated, with equivocal results (Jakobsson and Linberg 1983; Illingworth 1985; Moore et al. 1988). Stressful psychosocial factors may play a part (Rautava et al. 1993). The treatment includes reassurance about the benign nature of the symptoms. Massage of the abdomen, and patting the baby's back whilst he lies prone with the abdomen supported, appear to help, as do antispasmodic drugs (Weissbluth et al. 1984). Feeding technique should be checked, but giving up breastfeeding or changing the type of milk in bottle-fed babies is not justified without a clear reason.

Poor weight gain/persisting hunger

Bottle-fed babies receive ad libitum calories and fluid in measurable quantities, so this problem is much more common in breastfed infants, who, if denied adequate liquid and/or calories, will present with poor weight gain, persistent crying or both. If no other cause for these features is found, inadequate intake can be confirmed by careful test weighing. Checking the serum electrolytes may uncover hypernatraemic dehydration. If, despite implementing all the tricks outlined above to improve milk intake, the breastfed baby still fails to thrive, there comes a time when some extra source of liquid and/or calories is indicated. This time has come when:

- there is persistent failure to settle a crying and fractious breastfed baby over a short period of time

- the initial weight loss exceeds 10–12%
- there is dehydration, hypoglycaemia, hypernatraemia or severe jaundice (see Ch. 29.1)
- the baby has not regained birthweight by 10 days of age
- the mother has sore nipples or engorgement, only one breast is being used and the baby is hungry
- the mother is demoralised by a crying baby – calming the baby and offering help to correct poor positioning and attachment, with expression of milk, which can be given by cup, may transform the situation and allow normal lactation to be established.

One of the purported advantages of breastfeeding is a reduction in the incidence of cow's milk protein allergy (Host et al. 1988). There is the possibility that this syndrome may be induced even by one or two cow's milk formula feeds in the neonatal period. However, the evidence for this is weak, and the giving of glucose solution when breast milk is insufficient has little to recommend it. Moreover, there is no evidence that this practice decreases atopic disease in general (Gustafsson et al. 1992).

One may be forced into trying complementary and/or supplementary feeds in term babies with feeding problems, although the use of such feeds can make matters worse and cause lactation to fail completely. It may be, however, that the use of such feeds is the first objective marker of lactation that, for some reason or another, is unfortunately going to prove inadequate.

Dehydration fever

If a baby in the first week of life develops a fever, two likely and important causes are infection (Ch. 39.2) and overheating due to some defect in the environmental control (Ch. 15). If these are excluded in a febrile baby who appears well but has an inadequate intake and has lost 10% or more of his birthweight, he may be suffering from dehydration. This can be confirmed clinically, and by measuring the plasma osmolality, which in dehydration fever will usually exceed 310 mOsmol/l. Such a baby drinks clear fluids (or bottle milk) avidly, whereupon his temperature falls and he gains weight.

Gastroenterological symptoms

Vomiting (Ch. 29.4), diarrhoea (Ch. 29.3), abdominal distension (Ch. 29.3) and jaundice (Ch. 29.1) all require evaluation in their own right: they are rarely due to feeding problems, although jaundice is associated with breastfeeding.

Introduction

This chapter focuses on the care of well, small babies who are suitable for nursing on the special care baby unit (SCBU) or transitional care unit (TCU), including the convalescing neonatal intensive care unit (NICU) graduates.

The normal small baby

Traditionally babies weighing below the 10th centile have been regarded as small for dates, although babies with birthweights between the 3rd and 10th centile rarely pose a problem if clinically well and feeding adequately. Modern antenatal care usually distinguishes genuine intrauterine growth retardation (IUGR) from the normal small baby. IUGR babies are more susceptible than normal small babies to some of the complications of prematurity and are discussed in greater detail in [Chapter 10](#).

Special care baby units and transitional care units

Whenever possible small, well babies should be cared for on postnatal wards with their mothers. Babies separated from their mother at birth display separation distress calls which cease at reunion (Christensson et al. 1995) and separation from the mother on the first night may increase the risk of allergy in later life (Montgomery et al. 2000). The weight, gestation and other criteria which determine admission to the neonatal unit or TCU should be agreed locally between neonatal and postnatal ward staff. Typically, newborns less than 34 weeks' gestation or below 1.7 kg require NICU admission. Any baby who needs continuous monitoring and oxygen, or who meets other high-dependency criteria, will require SCBU admission.

Unfortunately, in recent years the availability of TCUs has declined, owing to lack of funds or appropriately trained staff. However, they remain popular with staff and parents (Simpson 2000) and may decrease the risks of mother–child separation and the risk of nosocomial infection. Nutritive sucking develops from around 32 weeks but regular sucking feeds are not usually established until 35 weeks, thus the necessity for tube-feeding is often the main factor requiring TCU admission and preventing discharge home (Table 21.1). The organisation of neonatal care is further discussed in Chapter 2.

Observations and monitoring on the transitional care unit

Routines, including clinical examination, cord care, screening, weighing and administration of vitamin K, are as for term babies – remembering that low-birthweight (LBW) babies should have intramuscular (not oral) vitamin K (Ch. 30). TCUs should be maintained at a stable temperature and contain essential equipment, including a fully equipped resuscitation area with piped oxygen, air and suction. The usual strict precautions to minimise nosocomial infection should apply (Ch. 39.2); each baby should have his or her own equipment, e.g. stethoscope, cotton wool and alcohol for hand rubbing.

Small and preterm babies have a greater risk of developing illnesses in the neonatal period (Engle et al. 2007) than mature

well-grown babies. The TCU is often the ideal place to monitor babies who are at risk of conditions which could make them unwell, e.g. meconium aspiration, sepsis (group B *Streptococcus* exposure or after prolonged rupture of the membranes), narcotic withdrawal and hypoglycaemia. The length and nature of observations for such conditions vary and are rarely standardised between units. Historically 'sepsis observations' or 'meconium observations' have been recorded for up to 48 hours, which may be undesirable for staff and families and are probably unnecessary. The current National Institute for Health and Clinical Excellence guideline on intrapartum care (2007, section 1.11.8) recommends observations of well-being, feeding, skin colour, perfusion, temperature, pulse and respiration at 1 and 2 hours of age and then 2-hourly intervals for 12 hours in well babies born through meconium-stained liquor. A suitable chart is reproduced in Figure 21.1. The modified Finnegan chart (Ch. 26) is used in many units to monitor babies at risk of narcotic abstinence syndrome (Ch. 26). All units need to adhere to strict guidelines for monitoring babies at risk of hypoglycaemia (see below and Ch. 34.1).

Temperature control

Small babies, with a larger surface area to body mass ratio than term babies, are prone to hypothermia. If the baby is in an ambient temperature below 22–23°C, he or she may be using the thermoregulatory mechanisms described in Chapter 15, which will place a metabolic demand on the baby (Azaz et al. 1992).

If a small baby has a temperature of 36.0°C or less on admission to the TCU, examine him or her and check that the baby is otherwise well. Check the baby is dry then fully clothe him or her, including a hat, before swaddling in a sheet and blankets. Extra heat can be provided from a radiant heater or heated mattress. If, despite adequate warming attempts, the baby remains hypothermic, or if a stable baby develops hypothermia, an evaluation is required to exclude sepsis and measurement of glucose levels. The baby's temperature should be rechecked after removing from a source of additional heat.

Hypoglycaemia (see Ch. 34.1)

The definition and pathophysiology of hypoglycaemia are discussed in more detail in Chapter 34 part 1. Preterm, small and IUGR babies are more likely to develop hypoglycaemia than term or appropriately grown babies. For healthy LBW and IUGR term or near-term babies, detection and prevention of hypoglycaemia by adequate feeding can be safely supervised in the TCU.

The blood glucose level at which adverse sequelae might arise is still uncertain. Some small babies have low glycogen stores and poor ketone body responses to hypoglycaemia. If the caloric intake is poor, then the baby is at risk of developing prolonged hypoglycaemia with a risk of adverse neurological sequelae. For an IUGR baby the risk of symptomatic hypoglycaemia is greatest between 24 and 48 hours of age, hence the importance of accurate and continued monitoring in this group, who are not generally suitable for transfer from hospital to community care before this vulnerable period has passed. Whole-blood glucometer readings, not reagent sticks, should be used for monitoring. Hypoglycaemia diagnosed on the ward using a glucometer should always be confirmed with a laboratory glucose level. Attempts should be made to keep the blood glucose above 2.0 mmol/l; this minimises the risk of developing severe hypoglycaemia (<1.0 mmol/l). There is no evidence that transient low levels of glucose, which are not associated with signs, cause any adverse long-term sequelae.

Table 21.1 Categories of babies suitable for transitional care

Low-birthweight babies and babies with intrauterine growth retardation
Convalescent neonatal intensive care unit graduates
Babies requiring close observation
Potential to develop symptoms of meconium aspiration, hypoglycaemia, drug withdrawal or sepsis
At risk of hypoxic–ischaemic encephalopathy, e.g. with poor cord gas but well following delivery
Infants of diabetic mothers
Babies with specific feeding difficulties
Cleft lip or palate
Requiring tube feeds (>3-hourly)
Babies requiring phototherapy
Twins and triplets of appropriate weight and gestation
Babies posing infection risk (if isolation cubicle available), e.g. gonococcal ophthalmia, <i>Listeria</i>

Hypoglycaemia: monitoring, prevention and treatment

For those at risk, feeds should be started as soon as possible after birth. The mother should be encouraged to hold her baby skin to skin and put the baby to her breast in the labour ward. In general, within the first 24 hours, every endeavour should be made to keep the blood glucose >2.0 mmol/l and thereafter above 2.5 mmol/l. Blood glucose monitoring should start at 4 hours of age (earlier if there is IUGR) and then every 4–6 hours until two consecutive levels are above 2.5 mmol/l. Monitoring should recommence if feeding is reduced or the baby is unwell. If there is difficulty keeping the blood glucose level above 2.0 mmol/l, an extra feed should be given by cup, bottle or tube and further investigations performed. A baby who cannot cope with breast, cup or bottle feeds should be tube-fed; syringe-/cup-feeding carries a high risk of aspiration (see below). If the glucose level remains low, or the baby has clinical signs or cannot tolerate feeds, then he or she should be admitted to the NICU.

Feeding on the transitional care unit

The following sections discuss the various methods of feeding. The route, type, frequency, volume and rate of increment of feeds vary widely and few good quality data exist to help inform practice. The mother should be involved as much as possible with the feeding of her baby and the ultimate method of feeding should be her preferred choice. The merits and nutritional aspects of the different types of milk are discussed in [Chapter 16](#).

Non-nutritive sucking

The sucking reflex develops from 28 weeks with effective suck, coordinated with breathing and swallowing, developing from 32 weeks and maturing fully by 35–37 weeks. Promoting non-nutritive sucking, using a pacifier or finger during tube-feeding, may help develop or maintain an effective sucking mechanism and decrease the length of hospital stay by easing the transition from tube to sucking feeds ([Symington and Pinelli 2006](#)).

Breastfeeding

If the mother intends to breastfeed the baby should, when possible, go to the breast in the delivery room soon after birth. Subsequently, regular breastfeeds help to stimulate colostrum and establish lactation. Preterm and LBW babies may need complementary feeds by cup, tube or bottle, until effective suckling feeds and weight gain are achieved. Monitoring for hypoglycaemia is often necessary for at least the first 48 hours or longer if the feeding is poor. Skin-to-skin contact, peer support, simultaneous breast milk pumping, multidisciplinary staff training and the Baby Friendly accreditation have been shown to improve successful breastfeeding ([Renfrew et al. 2009](#)).

Bottle-feeding

Breastfeeding should be encouraged when possible but if bottle-feeding is the desired, or required, method of feeding, ideally the baby should be demand-fed, aiming for a 3–4-hourly schedule and 6–8 feeds per day. If most of the required volume is taken and the baby is not hypoglycaemic, no further 'top-up' feed is necessary. One of the few advantages of bottle-feeding is that the exact volume of feed is known; if the baby is not taking enough, particularly if there are concurrent problems with hypoglycaemia or weight gain,

he or she should be topped up 3-hourly using a nasogastric tube. There is no firm evidence to support that using a teat causes 'nipple confusion' and the use of dummies has not been shown to affect breastfeeding.

Tube-feeding

Indications

The most common indication for tube-feeding is that a preterm or LBW baby is unable to suck the required amount of milk from the breast or bottle effectively. The decision to tube feed a baby is usually based on several factors, including:

- gestation at birth
- blood glucose levels
- frequency of waking for feed
- efficiency of sucking
- unsafe swallow
- inadequate volume taken
- dehydration, weight loss or paucity of weight gain.

Tube feeds can usually be administered on the TCU if they are not required more frequently than every 3–4 hours. Enteral feeding tubes may be placed via the nose or mouth. Evidence is lacking for superiority of either route ([Hawes et al. 2004](#)). Oral tubes are easier to pass but more prone to displacement, local irritation and vagal stimulation. Nasal placement may compromise respiration but the tubes remain in place more reliably. Breast- and bottle-feeding are both still possible with an indwelling nasogastric tube. Finger-feeding involves attaching a feeding tube to the side of a finger which is then inserted into the mouth in order to stimulate sucking. A breast supplementer is a similar device which may be attached to the breast whilst the baby sucks at the nipple and is another method that may encourage the baby to suck and swallow whilst breastfeeding is being established.

Complications of tube-feeding

Complications of tube-feeding in adults prompted the National Patient Safety Agency (NPSA), in consultation with the British Association of Perinatal Medicine, the Neonatal Nurses Association and the Royal College of Paediatrics and Child Health, to release guidance recommending that gastric tube position be confirmed by pH indicator strips, not litmus paper ([National Patient Safety Agency 2005](#)). Other methods, including X-ray, auscultation, the presence of respiratory distress and the appearance of aspirate, or bubbling, are not to be used to confirm position. Reported complications from tube-feeding in neonates are rare but include pharyngeal, oesophageal, gastric, duodenal and bladder perforation with pneumomediastinum and peritonitis ([Bell 1985](#); [Sands et al. 1989](#); [Mattar et al. 1997](#)). Soft silicone tubes have been passed into the bronchus ([Laing et al. 1986](#)). Gastro-oesophageal reflux has been shown to be almost universal in tube-fed preterm infants, increasing the risk of aspiration pneumonia ([Peter et al. 2002](#)).

Frequency and volume

In general, for preterm and small-for-gestational-age babies the volume given should be divided into a 3-hourly feeding schedule if there is normoglycaemia. Three-hourly feeds can usually be given on the TCU but if needed more frequently admission to SCBU is usually necessary. If the tube feed is complementing a bottle feed, the deficit should be made up. If the tube feed is complementing a breastfeed, in the first few days when only colostrum is likely to have been taken, the full volume should be given. Thereafter, a smaller proportion can be given based on clinical assessment.

Cup-feeding

Cup-feeding was reintroduced into the UK in the late 1980s by Sandra Lang. The technique involves swaddling the baby and sitting him or her in a semiupright position. The rim of a cup half-full of milk is then gently placed on the baby's lower lip, directing the rim towards the corners of the upper lip, tipping the milk to touch the baby's lip as he or she swallows it. Milk should not be poured into the baby's mouth. The method appears safe if carefully monitored, and breathing and oxygen saturation remained stable during one study of 15 cup-feeding sessions (Dowling et al. 2002). Cup-feeding involves sipping and lapping rather than sucking, thus breastfeeding should continue in order to enhance the sucking experience. Cup-feeding improves the likelihood of exclusive breastfeeding by discharge but increases the length of stay (Collins et al. 2008). Cup-feeding prolongs breastfeeding if frequent supplementary feeds are needed initially and following caesarean section (Becker et al. 2008). Cup-feeding is a useful adjunct to other methods of feeding, but is a short-term solution which carries a risk of aspiration if not carefully supervised. Milk spillage is a real problem, particularly when expressed breast milk is in short supply.

Milk expression and storage

For babies unable to suckle at the breast successfully, mothers should be encouraged and supported to start milk expression as early as possible. Physical and emotional stress to the mother may inhibit adequate milk production. Skin-to-skin nursing, multidisciplinary support and Baby Friendly accreditation have been shown to improve the chances of successful breastfeeding (Renfrew et al. 2009). Double pumping, skin-to-skin care and non-nutritive sucking at the breast can all help increase milk volume. Neonatal and maternity teams, with the help of lactation consultants, should support mothers to achieve this. Early (within 6 hours if possible), frequent (up to 10 times a day) and effective milk expression encourages maximum milk production. Adequately draining the breast is important as this stimulates further milk production and 'hind milk' has greater calorific value. If, despite frequent, effective expression, milk supply is inadequate, domperidone can increase maternal supply. Expressed breast milk can be safely stored in a refrigerator at less than 10°C for 3 days. It can be deep-frozen for 3 months and, once thawed, should be used within 24–48 hours.

Weight

All babies lose weight after birth – up to 10% of their bodyweight in the first 4–5 days – before gaining weight at 10–15 g/kg/day. It may take 6–10 days before the 32-week gestation, or 1.5–1.8-kg, baby shows steady weight gain.

Infection

Babies born at 32–35 weeks have physiological immunodeficiency (Ch. 39.1). They are born before the transplacental transfer of maternal immunoglobulin is complete and developmental maturity of lymphocyte function. Babies nursed in TCUs are susceptible to infection and strict nosocomial precautions should apply. If the baby has been delivered after prolonged rupture of the membranes, or other risk factors for neonatal infection are present (e.g. maternal factors, including pyrexia), then the baby requires evaluation with consideration of a full infection screen plus antibiotic treatment pending results (Ch. 39.2).

Skin

Skin integrity is an important barrier against infection. Tape should be thoughtfully applied and its use minimised as it is the primary cause of skin breakdown in LBW babies (Lund et al. 2001).

Jaundice

Small and preterm babies are more likely to develop jaundice, particularly if they are not feeding well or have been polycythaemic. If jaundice becomes apparent the bilirubin level and maternal blood group should be checked. Phototherapy should be instituted at bilirubin levels appropriate for gestation (Ch. 29.1), and a BiliBlanket can be chosen as first-line treatment in the preterm group. When assessing whether a jaundiced baby is fit for discharge many variables need to be considered, including postnatal age, gestation, weight gain/loss, feeding, bilirubin trend, rate of rise/fall and time since cessation of phototherapy. The bilirubin level should be checked for rebound 12–18 hours after ceasing phototherapy but the baby does not necessarily have to remain in hospital for this to be done.

Care of the intensive-care graduate

Babies who have required neonatal intensive care usually have a phase when they are well but still not ready for discharge. Satisfactory feeding and growth, maintenance of temperature at ambient room temperature and maintenance of adequate oxygen saturation levels without supplementary oxygen all need to be achieved before discharge, although a small number of NICU graduates with chronic lung disease (CLD) will be discharged still needing supplementary oxygen (Ch. 27.3). Convalescing NICU graduates in general remain well but routines should be in place to detect any new problems. Serious complications of prematurity, such as CLD (Ch. 27.3), retinopathy of prematurity (ROP: Ch. 33) and hydrocephalus (Ch. 40.5) are dealt with elsewhere in this book.

Routine surveillance

The NICU graduate needs a full examination once or twice a week. The routine should include the details listed in Table 21.2. Each week, full blood and reticulocyte count plus electrolyte, urea, calcium, phosphate and alkaline phosphatase levels should be assessed. The baby's bodyweight and head circumference should be plotted weekly on an appropriate chart to ensure normal progression. Cranial ultrasound follow-up assessments should continue at appropriate intervals (Ch. 40.5). New clinical findings which might arise during this time include hernia, anaemia, metabolic bone disease, murmurs, poor weight gain and cavernous haemangiomas.

Emotional, developmental and environmental needs, NIDCAP

The emotional and psychological needs of the baby and family continue to be important. Developmental programmes such as the Newborn Individualized Developmental Care and Assessment Program (NIDCAP) are increasingly popular and important, despite conflicting evidence of benefit (Pinelli and Symington 2005; Peters et al. 2009). The ethos of NIDCAP is to deliver individualised, developmentally supportive, family-centred care to optimise health and developmental outcome. Overall it would seem appropriate to

Table 21.2 Routine surveillance for the neonatal intensive care unit graduate

adopt a less 'chaotic, non-circadian environmental approach' in the modern neonatal nursery (Mirmiran and Ariagno 2000). Developmental care is further discussed in Chapter 4.

Feeding the convalescent premature baby

Many advantages result from the early introduction of minimal enteral feeding to very-low-birthweight (VLBW) babies even while they are still quite ill (Chs. 16, 29.3). Full enteral nutrition is achieved earlier, and the complications of long-term total parenteral nutrition are reduced (Ch. 17). By the time the baby is convalescent from the acute neonatal illness, he or she will usually be tolerating hourly feeds at a total daily volume of 150–180 ml/kg.

A large body of experience shows that, when introducing feeds, breast milk is better tolerated than formula (Ch. 16.3). Non-nutritive sucking using a pacifier during tube-feeding may have benefits (Symington and Pinelli 2006) and help train the baby in the techniques of sucking, although excessive pacifier use in the neonatal period may be detrimental to exclusive and overall breast-feeding duration (Becker et al. 2008). If well, once a baby is 30–32 weeks' gestation, he or she can be put to the mother's breast if she intends to breastfeed. Kangaroo mother care (Ch. 4), involving skin-to-skin contact, can help milk production. Once the baby is 33–34 weeks' gestation he or she should make a reasonable attempt at sucking feeds, and by 35 weeks most neurologically normal convalescent ex-premature babies should be able to suck and swallow safely. For those mothers who have maintained their lactation by expression, every attempt should be made to encourage the baby to go to the breast, and if possible to have the mother rooming in or on the TCU.

Nutritional supplements

Sodium

Hyponatremia is common, particularly in breastfed babies, as breast milk lacks adequate amounts of sodium for the needs of the preterm baby (Ch. 16.3). In addition the fractional excretion of

sodium is relatively high (Chs. 18, 35.1). Sodium supplements should be given; some babies need up to 10 mmol/kg/day.

Phosphate and vitamin D

Extremely low-birthweight (ELBW) babies are at risk of metabolic bone disease (see Ch. 35.4), which manifests biochemically as hypophosphataemia, elevated alkaline phosphatase and occasionally, in severe cases, hypercalcaemia. Vitamin D supplementation, 4–800 units daily often given as part of a multivitamin supplement, with appropriate phosphate supplements (approximately 0.5 mmol/100 ml breast milk), reduce the risk of metabolic bone disease (Ch. 34.4).

Iron and folic acid

VLBW babies are born before most of the body's stores of iron are laid down in the third trimester of pregnancy. Supplements of enteral iron 2–3 mg/kg/day should be started at 2–6 weeks of age (ESPGHAN Committee on Nutrition 2010) but delayed until 4–6 weeks in infants who receive multiple blood transfusions as excessive iron has been associated with increased risk of infection and poor growth (Domellof 2007). Preterm babies receiving entirely breast milk may become folate-deficient and develop megaloblastic anaemia (Strelling et al. 1979). Most NICUs give 100 µg folic acid daily until term corrected for gestational age, or until discharge.

Growth and weight gain

The standard rules of neonatal weight gain apply. Babies should gain weight at roughly 15 g/kg/day. The baby may feed voraciously, particularly towards the end of the convalescent phase in the neonatal unit and may take more than 180–200 ml/kg/day. This sort of catch-up growth is frequently seen once the baby goes home and the parents are much less rigid than the nursing staff, feeding volumes of up to 300 ml/kg/day (Lucas et al. 1992). Not uncommonly peripheral, rather firm, oedema may develop, which can cause concern but no diuretics or other treatment is required.

Table 21.3 Causes of poor weight gain

Inadequate caloric intake
Expressed breast milk
Vomiting
Low-volume feeds
Insufficient supply of essentials other than energy
Sodium deficiency
Anaemia (inadequate oxygen-carrying capacity)
Increased energy expenditure
Bronchopulmonary dysplasia
Sepsis
Hyperactivity
Thyrotoxicosis
Cerebral irritability
Seizures
Drug withdrawal
Drug therapy
Diuretic
Cold stress
Bathing, handling, inadequate clothing
Misery
Lack of non-nutritive sucking
Discomfort
Excessive nutrient losses
Short-bowel syndrome
Gastro-oesophageal reflux
Hypertrophic pyloric stenosis
Necrotising enterocolitis
Gastroenteritis
Protein-energy malnutrition
Milk lactose and protein intolerance
Congenital enteropathies

Poor weight gain (Table 21.3)

The commonest cause of poor weight gain is inadequate caloric intake. Intake should be increased to a volume of 180–200 ml/kg/day of breast milk if tolerated, and if the mother is producing large volumes of milk the hind milk may contain more fat than the fore milk. If weight gain remains poor, then appropriate supplements should be considered, usually breast milk fortifier but occasionally supplementary feeds (Ch. 16.3). CLD, anaemia and hyponatraemia also cause poor weight gain. If, despite adequate calorie, sodium and nutrient intake, weight gain remains poor, other causes of failure to thrive should be considered (Table 21.3).

Head growth and shape

Weekly occipitofrontal circumference measurement is important. Accelerated growth might be due to hydrocephalus (Ch. 40.5) and slow growth may indicate cerebral atrophy. Preterm babies may develop a long thin dolichocephalic head shape as the relatively immobile baby with soft skull bones lies predominantly on one side (Cartlidge and Rutter 1988). This can be minimised by appropriate positioning but even without intervention the head shape

normalises spontaneously (Rutter et al. 1993). Since supine sleeping has been advocated to decrease the risk of sudden infant death syndrome (SIDS), plagiocephaly, particularly brachycephaly to the right, and torticollis have increased (Hummel and Fortado 2005).

Anaemia of prematurity

The preterm baby often becomes anaemic, with a haemoglobin nadir of 7–9 g/dl at 6–8 weeks of age. The aetiology of the condition is multifactorial (Ch. 30) including iatrogenic blood loss at a time when the rapidly expanding intravascular volume may outstrip the bone marrow's capacity to produce sufficient red cells. If the baby is well and breathing air, a haemoglobin can be allowed to remain as low as 7 g/dl without transfusion, particularly if the reticulocyte count (3–10%) is reassuring. If symptoms of anaemia such as poor feeding, lethargy or congestive heart failure (Alvarson 1995) occur, the baby may benefit from 15 ml/kg transfusion of packed red cells.

Data reporting the effects of transfusion on apnoea are conflicting. Some authors conclude that transfusion decreases the frequency of apnoea (Stute et al. 1995). However, others suggest that transfusion has little effect on apnoea but tachycardia and tachypnoea may be significantly improved (Westkamp et al. 2002).

VLBW babies may have a marked eosinophilia by the age of 3–4 weeks. This often follows an episode of proven sepsis (Manoura et al. 2002) but is otherwise a benign finding.

Murmurs

During the convalescent period, a heart murmur may be noted for the first time. Murmurs associated with cardiac failure, cyanosis or decreased femoral pulses need prompt investigation. Mild pulmonary artery stenosis may be noted as a soft ejection systolic murmur. Once confirmed, this benign murmur does not require further investigation and resolves as the baby grows (Arlettaz et al. 2001).

Hernias and testes

Inguinal hernias occur in 11% of babies under 1500 g and 17% under 1000 g, and they are more likely to occur in boys and in babies with CLD (Kumar et al. 2002). Hernias should ideally be repaired prior to discharge but the timing of surgery is a matter of clinical judgement. Repairing large hernias in babies with severe CLD can result in serious deterioration; other babies with CLD may have improved respiratory status following repair (Emberton et al. 1996). There is no need to rush into surgery for cosmetic reasons. Spinal anaesthetic may decrease the risk of postoperative events (Libby 2009).

Delayed descent of the testes is very common in ELBW babies. No specific treatment is indicated, but, if the testes are still not descended by the time of discharge, appropriate follow-up should be arranged with a paediatric surgeon.

Umbilical hernias are common, especially in babies with Down syndrome, Afro-Caribbean babies and those with CLD. They invariably resolve but may become large; if still present at 1 year of age, referral should be made to a paediatric surgeon.

Retinopathy of prematurity (see Ch. 33)

All babies less than 32 weeks' gestation and below 1500 g birth-weight require assessment to exclude ROP (Royal College of Paediatrics and Child Health, Royal College of Ophthalmologists, British Association of Perinatal Medicine and Bliss 2008). Many units perform this at 4–5 weeks of age for all eligible babies. The

examination can destabilise the sick baby and care should be taken when giving a mydriatic with systemic side-effects, e.g. bradycardia and arrhythmias.

Hearing

Since 2003 the Newborn Hearing Screening Programme ensures parents of all newborns are offered hearing screening in the first weeks of life. These tests are very important for NICU graduates who are at increased risk of hearing deficit owing to either illness, e.g. hypoxia and sepsis, or drug treatment. Deafness due to aminoglycoside or furosemide toxicity is very rare in clinical practice and there has been recent discovery of genetic susceptibility to aminoglycosides. A mitochondrial mutation (the m.1555A>G mutation) renders individuals susceptible to gentamicin ototoxicity, and in this situation the high sensitivity to gentamicin means that exposure to levels which are well within the therapeutic range can result in hearing loss; some affected individuals become deaf without any gentamicin exposure at all.

Discharging small babies

Traditionally there has been a focus on the need to attain a particular weight before discharge but the advent of neonatal community nurses has made such rules more flexible (Merritt et al. 2003; Rose et al. 2008). The process of discharge planning should start soon after admission. Coordinated individualised discharge planning programmes involving the family, including plans for structured home visiting, are successful and popular (Bliss 2009; POPPY Steering Group 2009). The recommendations of the American Academy of Pediatrics (2008) are helpful:

- a sustained pattern of weight gain rather than a specific achieved weight
- physiological stability
- the ability to suck some feeds and maintain normal body temperature in an open environment
- parental involvement and preparation prior to discharge
- home support post discharge
- outpatient follow-up to ensure adequate weight gain and to monitor development.

Apnoeic episodes may occur up to 8 days apart in otherwise well babies, thus an interval of this length from the last apnoea is recommended before discharge (Darnall et al. 1997). The British Thoracic Society advocates discharge for infants with CLD when their oxygen requirement is stable with mean saturation of 93% or above and without frequent episodes of desaturation (Balfour-Lynn et al. 2009). Further management of the baby requiring home oxygen for CLD is discussed on Ch. 27.3.

Prior to discharge, each baby should have a complete neonatal examination, including visualisation of the normal red light reflex and examination of the hips to assess stability (Ch. 37). Hearing screening plus ROP checks for those who qualify should be performed and follow-up arranged if indicated.

Advice to parents

Written information and useful website addresses can help parental understanding and preparation prior to discharge (Bliss 2009; POPPY Steering Group 2009). Preterm infants have 8–10 times the risk of SIDS compared with low-risk term babies and advice aimed at decreasing the risk of SIDS should include recommendations for the baby to sleep on his or her back in a cigarette-free environment

and not to be overwrapped (Fleming et al. 1996). Parents are advised not to sleep in the same bed as the baby, especially if they smoke, have recently drunk alcohol, are very tired or are taking drugs which make them sleepy. A baby under 8 weeks old sharing a bed with parents has a twofold increased risk of SIDS if the parents are non-smokers and 11-fold if the parents smoke (Carpenter et al. 2004). The baby's cot should probably be in the parents' bedroom until 6 months of age (Fleming et al. 1996).

Monitors

Although preterm babies are more likely than term babies to have adverse cardiorespiratory events until 43 weeks' corrected gestational age, there is no evidence that these events are precursors to SIDS, and after 43 weeks' corrected gestational age, the frequency of cardiorespiratory events in preterm babies is the same as for healthy term babies (Rangasamy et al. 2001). There is no evidence that the incidence of SIDS or acute life-threatening events is reduced by home apnoea alarms and it is possible that many cardiorespiratory events are missed by standard monitors.

Flying

Parents often want to know if their baby is 'fit to fly'. Infants under 1 year are more susceptible to hypoxia resulting from flight cabin pressurisation, especially if they were born preterm or have CLD. It is generally believed flying is safe in the first year of life for most healthy infants but for those at risk preflight testing with a 'fitness to fly' test, available in some tertiary centres, can help guide the need for in-flight supplemental oxygen (Bossley and Balfour-Lynn 2007).

Car seat testing

Infants under 2 kg are at increased risk of altered breathing pattern, desaturation or bradycardia in a car seat, which improves when the infant is supine; thus car seat testing may be wise for this group of babies (Ojadi et al. 2005).

Resuscitation training

Teaching parents resuscitation procedures helps alleviate anxiety and increase parental confidence (Dracup et al. 2000); however, there is no evidence that resuscitation training reduces post discharge mortality or morbidity. Additional video instruction, as produced by the charity Bliss and the American Heart Association, is associated with improved performance (Brannon et al. 2009).

Feeding and supplements

Breastfeeding should be the preferred option and discharge planning should include plans to achieve full breastfeeding, with an adequate support network. Exclusive breastfeeding to 6 months of age is safe and beneficial (Kramer and Kakuma 2002). Breast milk or hydrolysed formula in preference to intact cow's milk protein formulas may delay the onset of childhood atopic disease (Frank et al. 2008). Post discharge nutrition and follow-on formulas for the NICU graduate are discussed in Ch. 16.3.

The NICU graduate should receive iron and vitamin D supplementation from the time of discharge until at least 6 months of age. For the breastfed preterm TCU graduate, similar supplementation should be given but, as all formulas are now supplemented, it is doubtful whether additional vitamins and iron are required for bottle-fed babies.

Immunisations

Premature babies are at increased risk of vaccine-preventable infections and should be vaccinated according to the recommended schedule without correction for prematurity (Department of Health 2006). In addition after 6 months of age, but before the 1st winter influenza season starts, infants with oxygen dependent CLD should receive two doses of the influenza vaccine, 1 month apart. Annual repeats are only necessary if the infant remains oxygen dependent. Also babies with CLD, particularly those going home on oxygen, should receive palivizumab respiratory syncytial virus prophylaxis during their first winter and, if they remain on oxygen, prophylaxis until 2 years of age is advised (Department of Health 2005).

The evidence base for immunisation of preterm infants is limited; however, the available data support early immunisation without correction for gestational age (Bonhoeffer et al. 2006). For a number of antigens the antibody response to initial doses may be lower than that of term infants, but protective concentrations are often achieved and memory successfully induced. The 2–3–4-month schedule may be preferable for immunisation of preterm infants in order to achieve protection as early as possible. There is no evidence that delaying vaccination for babies who have received steroids is beneficial. An additional dose may be required to achieve persistence of protection, particularly for babies who have received steroids for CLD.

Adverse events following immunisation are increased in premature infants, particularly if there is a pre-existing tendency to episodes of cardiorespiratory instability such as apnoea or desaturations (Pfister et al. 2004), thus delaying immunisation until stability is sensible. Adverse incidents do not appear to be related to gestational age and are unlikely after 48 hours following immunisation. Warning parents about possible adverse events can help to alleviate parental anxiety. Minor adverse events include low-grade fever, soreness at the injection site and malaise. Vaccination also causes a rise in the C-reactive protein (Balkundi et al. 1994). Prophylactic paracetamol decreases the risk of fever but should not be routinely administered as it reduces antibody responses to several antigens (Prymula et al. 2009).

Post discharge support and follow-up

Parents of babies with significant ongoing medical concerns, including oxygen-dependent CLD, are often given 'open access' letters or

Table 21.4 Criteria for outpatient follow-up of neonatal intensive care unit graduates

≤30 weeks' gestation
<1.50 kg birthweight
Neonatal encephalopathy
Seizures
Meningitis
Septicaemia
Necrotising enterocolitis
Significant hyperbilirubinaemia (including those requiring exchange transfusion)
Abnormalities on cranial ultrasound scan
Persisting murmurs
Persisting structural abnormalities, e.g. hernia, vesicoureteric reflux, undescended testicles
Babies with chronic lung disease at discharge
Babies whose families have social problems, e.g. narcotic abuse
Infants of human immunodeficiency virus-positive mothers

'parents' passports' to allow direct admission to the paediatric services should the need arise. Appropriate telephone numbers for the community support team plus access to 24-hour advice are needed. Initially this advice might be given from the neonatal team who are familiar to the family and every effort should be made to document the calls and advice given. NICU wards rarely have the facility to record incoming calls but some community teams may have recordable phones, especially if messages need to be left. Responsibility for supporting the families of infants with long-term needs is often transferred to the paediatric community nurses at or soon after discharge.

A baby discharged from the TCU who had an uncomplicated course may not need hospital follow-up. The routine child health surveillance system is adequate for the needs of many of these babies. Most NICU graduates require follow-up, but it is important to be selective (Table 21.4). Careful multidisciplinary follow-up is necessary for babies with potential or actual complex problems so that motor delay, spasticity and poor weight gain are detected and managed promptly. Long-term follow-up of babies who have been very sick or premature, with accurate data collection, helps consolidate epidemiological information about outcome. The current UK recommendations are for all babies born at <32 weeks gestation to be assessed at 2 years (Lyon 2007).

Outcome	391
Avoiding harm	391

Diabetes may predate pregnancy or a woman may develop transient or permanent diabetes during pregnancy. The fertility and well-being of women with diabetes dramatically improved with the availability of insulin, but a high perinatal mortality rate of 20–25% persisted until the 1960s. In the last three decades perinatal mortality rates have fallen, but these vary between countries and regions and progress against aspirations has been disappointing, with a neonatal death rate in the UK of 9.3 per 1000 births, 3.8 times the national rate (Table 22.1) (Roversi et al. 1979; Hunter 1992; Casson et al. 1997; Hawthorne et al. 1997; Confidential Enquiry into Maternal and Child Health 2005; Hawdon 2010).

When there is good preconceptional care and control of diabetes and in the absence of congenital abnormalities or other

complications, babies should be managed as any other healthy term baby (National Collaborating Centre for Primary Care 2006). There is no indication for routine attendance of paediatricians at the delivery or routine admission to a neonatal unit (Confidential Enquiry into Maternal and Child Health 2005, 2007a, b; National Institute for Health and Clinical Excellence 2008).

However, there may be complications for the fetus and in the newborn. Some neonatal complications are not specific to diabetes in pregnancy, but relate to being born preterm or by caesarean section (Confidential Enquiry into Maternal and Child Health 2005; Hawdon 2010) and are covered elsewhere in this book. These will be minimised by careful consideration of timing of delivery, maternal steroid administration prior to preterm delivery and reduced rate of unnecessary caesarean sections. Other complications are secondary to the abnormal metabolic environment of the fetus and ongoing disturbances postnatally and are more specific to diabetes in pregnancy (Table 22.1). Of women who have prepregnancy diabetes, approximately one-third have type 2 diabetes, and the incidence and nature of complications do not vary according to type of diabetes (Confidential Enquiry into Maternal and Child Health 2005; Bell et al. 2008). Adequate antenatal screening and assessment should identify the pregnancies at greatest risk so that a management plan may be made, and the baby should be born in a centre where there are staff trained to manage unexpected complications.

Before discussing the aetiology and management of the fetal and neonatal complications of maternal diabetes, it is appropriate to be reminded of Farquhar's vivid and classic description of babies born after diabetes in pregnancy (Farquhar 1959):

They emerge at least alive from within the fiery metabolic furnace of diabetes mellitus, but they resemble one another so closely that they might well be related. They are plump, sleek, liberally coated with vernix caseosa, full-faced and plethoric. During their first two or more extrauterine hours they lie on their backs, bloated and flushed, their legs flexed and abducted, their lightly closed hands on each side of the head, the abdomen prominent and their respiration sighing. They convey a distinct impression of having such a surfeit of both food and fluid pressed upon them by an insistent hostess that they desire only peace so that they may recover from their excesses.

Table 22.1 Neonatal outcomes in the UK

	CEMACH COHORT	UK	RATE RATIO
Neonatal death	9.3/1000	3.6/1000	2.6
Preterm delivery	37%	7.3%	5
Congenital anomaly	5.5%	2.1%	2.6
Birthweight >90th centile	52%	10%	5.2
Shoulder dystocia	7.9%	3%	2.6
Erb's palsy	4.5/1000	0.42/1000	11
Apgar <7 at 5 min	2.6%	0.76%	3.4
Admission NNU	56%	10%	5.6
Term admission SC	33%	10%	3.3

NNU, any admission to a neonatal unit, all levels of care; SC, admission of a term baby to a neonatal unit, special care only: 67.1% of these were assessed to be avoidable.
 Data from Confidential Enquiry into Maternal and Child Health (CEMACH) survey (2005).

Congenital abnormalities

Despite major improvements in the care of diabetes in pregnancy, there has been little overall change in the incidence of congenital anomalies (Molsted-Pedersen et al. 1964; Casson et al. 1997; Confidential Enquiry into Maternal and Child Health 2005; Hawdon 2010). Congenital anomalies in the offspring of women with diabetes occur with a frequency up to 10 times that observed in the general population. Congenital anomalies (along with intrapartum causes) now account for a large proportion of perinatal losses and have replaced respiratory distress syndrome (RDS) as the leading cause of perinatal loss (Damm and Molsted-Pedersen 1989; Casson et al. 1997; Confidential Enquiry into Maternal and Child Health 2005, 2007a).

The cause of diabetic embryopathy is not fully understood. Genetic factors (diabetes-related genes) are unlikely to play a role, as the incidence of birth defects is not increased in babies of fathers with diabetes (Comess et al. 1969). Also, insulin cannot be teratogenic, because the human placenta is impermeable to insulin at early gestation (Adam et al. 1969) and fetal pancreatic β cells are not present before the 10th week (Like and Orci 1972). It is likely that congenital anomalies are related to the diabetic intra-uterine environment during the period of organogenesis, before the seventh week of gestation (Mills et al. 1979). Therefore, most occur before the pregnancy is recognised and the intensified diabetes treatment is initiated. Possible contributory factors are hyperglycaemia (Freinkel 1988; Miodovnik et al. 1988), hyperketonaemia (Horton and Sadler 1983; Sadler et al. 1989), increased levels of somatomedin-inhibiting factors (Sadler et al. 1986), decreased myoinositol concentration in the neuroectoderm (Sussman and Matschinsky 1988) and disturbances in the secretion of relaxin, an insulin homologue (Edwards and Newall 1988). Finally, hypoglycaemia can also be embryotoxic in experimental animals (Buchanan et al. 1986) but data from human studies are reassuring (Miodovnik et al. 1988).

Anomalies overrepresented in pregnancies complicated by diabetes are caudal regression syndrome (Passarge and Lenz 1966;

Coombs and Kitzmueller 1991), neural tube defects, holoprosencephaly (Barr et al. 1983), vertebral dysplasia, congenital heart disease, ventricular septal defect, transposition of the great vessels and small left colon syndrome (Philippart et al. 1975; Confidential Enquiry into Maternal and Child Health 2005).

It is clear that efforts to prevent birth defects should start before conception, with contraceptive advice offered so that every pregnancy can be planned in advance with optimum periconceptual metabolic control. Some reports suggest that early first-trimester improvement in glycaemic control (Fuhrmann et al. 1983; Edwards and Newall 1988; Diabetes Control and Complications Trial Research Group 1993) combined with prenatal diagnosis of anomalies using serum α -fetoprotein determinations and ultrasound scanning (Molsted-Pedersen and Pedersen 1985) could reduce the impact of congenital anomalies.

Obstetricians and neonatologists must ensure that there has been adequate counselling of parents, involving the specialist team who will care for the baby postnatally, and that delivery takes place at an appropriate centre (dependent on the nature of the anomaly) to enable early access to specialist care. Routine postnatal echocardiography to screen for congenital heart anomalies is not indicated, unless an abnormality has been suspected on antenatal scanning or the baby presents with clinical signs of congenital heart disease (National Institute for Health and Clinical Excellence 2008).

Macrosomia

'Macrosomic' and 'large-for-gestational-age' are not interchangeable terms. Macrosomia describes a baby who is heavier than his or her genetically determined birthweight and the clinical appearance of a baby who has had somatic growth in excess over head growth, and thus may be present in a baby of 'normal' birthweight.

Macrosomia and organomegaly attributed to fetal hyperinsulinaemia are well-known characteristics of pregnancy complicated by diabetes (Confidential Enquiry into Maternal and Child Health 2005; Hawdon 2010). Glucose crosses the placenta by facilitated diffusion, therefore maternal hyperglycaemia imposes a carbohydrate surplus on the fetus. The fetus responds with increased secretion of insulin. Because insulin is an anabolic hormone the fetal hyperinsulinaemia stimulates protein, lipid and glycogen synthesis to cause macrosomia. Although this classic maternal hyperglycaemia–fetal hyperinsulinism theory of Pedersen (1954) is widely accepted, the metabolic and endocrine disturbances are much more complex. For example, free amino acids also have a stimulatory effect on the development of the β cell, and the anabolic actions of insulin, in utero at least, could in part be mediated through the insulin-induced release of insulin-like growth factors (Milner 1988). In addition, birthweight is positively correlated with maternal concentrations of triglycerides and free fatty acids (Knopp et al. 1992).

Rates of macrosomia vary between centres; for example, from only 8% with birthweights above the 90th centile in an Italian study of strict maternal diabetic control to 52% with birthweights above the 90th centile in the recent UK cohort (Roversi et al. 1979; Hawthorne et al. 1997; Confidential Enquiry into Maternal and Child Health 2005). There is no direct relationship between overall maternal diabetes control and macrosomia (Bradley et al. 1988) – some babies are born with macrosomia after a pregnancy in which maternal blood glucose levels were well controlled. The reason for this may include the fact that glucose level is not the only parameter describing optimal diabetic control in pregnancy. However associations of birthweight with maternal glucose levels (even when not excessively raised) and cord blood C peptide levels have been

Fig. 22.1 An infant born after poor control of maternal diabetes. There is increased adiposity and facial plethora, together with respiratory distress.

reported. Enhanced control of even mild gestational diabetes is associated with reduced fetal overgrowth and risk of shoulder dystocia (Hod et al. 1996; Mello et al. 2000; HAPO Study Cooperative Research Group 2008; Landon et al. 2009).

The striking physical appearance (Fig. 22.1) of macrosomic infants has already been described. Much of the increased mass is fat (Whitelaw 1977). The organomegaly is selective, the liver and heart are often enlarged and skeletal length is increased in proportion to weight, but the brain size is not increased relative to gestational age and so the head may appear disproportionately small (Naeye 1965).

The clinical significance of macrosomia is the risk of the complications of delivery of a large infant, such as shoulder dystocia, obstructed labour, perinatal asphyxia and birth injury (e.g. brachial plexus injury or fractured clavicle or humerus) (Acker et al. 1985; Mimouni et al. 1988; Confidential Enquiry into Maternal and Child Health 2005).

Finally, parents and health professionals must be prepared for 'catch-down' in postnatal growth of macrosomic babies, especially when breastfed. This is a normal and healthy adaptation and, provided the baby appears to be feeding well and is healthy, there should be no concern if there is an initial period of slow weight gain such that weight crosses down centile lines (Owen et al. 2006, 2008).

Hypertrophic cardiomyopathy

Cardiac enlargement and hypertrophy in babies of diabetic mothers were reported as early as 1944 (Miller et al. 1944). The condition has now been studied more extensively (Soltész et al. 1978). Improved echocardiographic techniques have shown a generalized myocardial hypertrophy with a disproportionate thickening of the septum (Mace et al. 1979; Reller and Kaplan 1988; Veille et al.

Fig. 22.2 Echocardiographic image of a four-chamber view of a neonatal heart, demonstrating hypertrophy of the intraventricular septum (IVS) secondary to fetal hyperinsulinism. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

1992). Symptomatic infants generally have severe hypertrophy with hypertrophied septal muscles bulging into the left ventricle, thereby narrowing the left ventricular outflow tract (Fig. 22.2). Although the condition is transient it may cause fetal or neonatal death (McMahon et al. 1990; Sardesai et al. 2001). The cardiomyopathy has been related to maternal diabetes control (Mace et al. 1979; Reller and Kaplan 1988) and to fetal and neonatal hyperinsulinaemia (Breitwieser et al. 1980). Resolution of the signs can be expected in 2–4 weeks, and the septal hypertrophy regresses within 2–12 months (Way et al. 1979; Reller and Kaplan 1988) (see also Ch. 28).

If clinical signs occur, the presentation is usually within the first weeks of postnatal life with cardiorespiratory distress and congestive heart failure. Systolic ejection murmurs can be heard in most affected infants, and chest radiography reveals cardiomegaly (Way et al. 1979). The majority of the infants need supportive care only. If congestive heart failure develops, propranolol is recommended. (Way et al. 1979). Digitalis and other positive inotropic agents are generally contraindicated because they increase systolic contraction and may exacerbate the outflow tract obstruction (Way et al. 1979).

Intrauterine growth restriction

Maternal vascular disease may complicate diabetes and lead to placental insufficiency and impaired fetal growth, so some infants will be born small-for-gestational-age (Cordero and Landon 1993). Overzealous diabetic control and maternal hypoglycaemia may have the same result (Langer et al. 1989). The small-for-gestational-age infant of the diabetic mother appears to be at even greater risk of adverse outcome, especially neurodevelopmental sequelae (Petersen et al. 1998), because the perinatal problems associated with diabetes in pregnancy are compounded by those of intrauterine malnutrition (see Ch. 10).

Effects of antenatal and intrapartum hypoxia–ischaemia

Stillbirth, encephalopathy, hyperviscosity, polycythaemia, jaundice

The mechanism for increased risk of significant fetal hypoxia–ischaemia during diabetes in pregnancy is not fully understood. In the UK cohort of diabetes in pregnancy, 10% of perinatal deaths were related to intrapartum causes (*Confidential Enquiry into Maternal and Child Health* 2005, 2007a). In addition, there will be many babies affected by intrapartum hypoxia–ischaemia born alive and requiring expert resuscitation. This is one of the reasons why delivery after diabetes in pregnancy must occur in units where expert advanced neonatal life support is available. If a neonate has unexpected and severe complications of hypoxia–ischaemia the baby will require transfer to a neonatal unit which provides intensive care, if this is not available in the hospital of birth. As total body cooling becomes an established treatment for hypoxic–ischaemic encephalopathy, transfer for this treatment at a specialist centre should be considered (*Jacobs et al.* 2007).

Infants born after diabetes in pregnancy have an increased risk of being polycythaemic and developing neonatal hyperviscosity syndrome (*Mimouni et al.* 1986). Normoblastaemia and extensive extramedullary erythropoiesis were observed as early as 1944 (*Miller et al.* 1944) and the aetiology of the increased erythropoiesis has since been described (*Phillips et al.* 1982). Elevated umbilical plasma erythropoietin concentrations have been correlated directly with plasma insulin levels in both infants of diabetic mothers (IDMs) and controls (*Widness et al.* 1981). The raised erythropoietin levels are thought to be secondary to relative cellular hypoxia, which is the result of insulin-induced high glucose uptake and high metabolic rate. A more direct effect of insulin was shown in another study in which insulin stimulated growth in culture of late erythroid progenitors in cord blood from premature infants, term infants and IDM (*Perrine et al.* 1986).

Lysis of this red cell load contributes to the prolonged unconjugated hyperbilirubinaemia often found in IDMs. There may also be functional immaturity of hepatic enzymes (*Stevenson et al.* 1981).

Renal vein thrombosis and thrombosis in other vessels, which has been reported to occur with increased frequency in IDMs, is probably related to polycythaemia and hyperviscosity (*Avery et al.* 1957).

Polycythaemia and hyperbilirubinaemia should be managed as described elsewhere in this book.

Respiratory complications

Although the incidence of RDS was previously reported to be 5–6 times higher after diabetes in pregnancy than in the normal population, this incidence is falling in line with improved control of diabetes and prevention of preterm delivery (*Hanson and Persson* 1993). Rarely, babies born after diabetes in pregnancy have typical RDS despite a normal lecithin–sphingomyelin ratio in the amniotic fluid. This may be because RDS is secondary to the retarded maturation of the pulmonary surfactant system, including surfactant proteins (*Carlson et al.* 1984; *Nogee et al.* 1988; *Gewolb* 1993), rather than simply to the reduced production of phospholipids. Animal studies have demonstrated that insulin inhibits cortisol-induced lecithin synthesis by pneumocytes, probably by inhibiting the production of fibroblast–pneumocyte factor, which promotes phosphatidylcholine synthesis (*Smith et al.* 1975). It has also been

demonstrated that butyrate inhibits the transcription of mRNA for surfactant proteins (*Peterec et al.* 1994).

There is also an increased risk for transient tachypnoea of the newborn (*Hanson and Persson* 1993) or respiratory distress associated with cardiac abnormalities. Finally, many babies are delivered before term and/or by caesarean section, and the contribution of these factors to increased respiratory morbidity from RDS or transient tachypnoea of the newborn must be considered (*Morrison et al.* 1995). The management of these respiratory complications, should they occur, should be as recommended elsewhere in this book.

Hypocalcaemia and hypomagnesaemia

Neonatal hypocalcaemia has been reported in up to 50% of babies born after diabetes in pregnancy (*Tsang et al.* 1972; *Mimouni et al.* 1986) and both its incidence and severity appear to be related to diabetes control (*Tsang et al.* 1972; *Demaini et al.* 1994). Hypocalcaemia is usually associated with hyperphosphataemia and occasionally with hypomagnesaemia. The aetiology is not entirely clear, but neonatal hypoparathyroidism has been demonstrated and may in part be secondary to maternal magnesium loss (*Mimouni et al.* 1989; *Demaini et al.* 1994; *Martinez et al.* 1994). Perinatal hypoxia–ischaemia may also exacerbate hypocalcaemia.

No published study has commented upon the clinical significance of hypocalcaemia or hypomagnesaemia. Usually no clinical signs are seen and no treatment is necessary.

Disordered postnatal metabolic adaptation (see Ch. 34.1)

Almost all babies, regardless of circumstances of pregnancy, manifest a period (of some hours postnatally) of asymptomatic hypoglycaemia before a spontaneous increase in blood glucose level occurs. This is more prolonged or becomes clinically significant for some babies born after diabetes in pregnancy (*Persson* 2009). However, all regain normal blood glucose control within the first few days after birth. For the full definition and symptoms of hypoglycaemia, see Ch. 34.1. It is likely that plasma insulin levels fall to normal within 12–24 hours of birth in all infants except those whose mothers' diabetes was poorly controlled (*Hawdon and Aynsley-Green* 1996). Where maternal blood glucose levels are raised but below the diagnostic level for diabetes, there is only a marginal and barely significant relationship between maternal fasting blood glucose levels and incidence of neonatal hypoglycaemia (*HAPO Study Cooperative Research Group* 2008).

Hyperinsulinism at birth is the result of increased placental transfer of glucose and other nutrients stimulating increased fetal insulin secretion (see above) (*Block et al.* 1974). The pancreas shows hyperplasia and hypertrophy of the islets of Langerhans (*Miller et al.* 1944; *Cardell* 1953) without evidence of pancreatic pathology. An increase of the glucagon and pancreatic polypeptide cell fractions in the pancreas has also been shown by immunocytochemical methods (*Miller et al.* 1944) and a counterregulatory hormone response has been demonstrated which is likely to curtail the period of hypoglycaemia (*Milner et al.* 1981; *Broberger et al.* 1984; *Hertel and Kuhl* 1986). However, it has been reported that some infants fail to develop the normal increase in plasma glucagon at 2–4 hours of age (*Bloom and Johnston* 1972).

The effect of hyperinsulinism on the liver has been confirmed using stable isotope methods (*Kalhan et al.* 1977) which

demonstrated decreased glucose production. If raised insulin levels persist beyond the first postnatal day, other metabolic fuels may be affected. For example, in theory plasma free fatty acid and blood ketone body concentrations may be lower than in normal term infants, although clinical studies have not confirmed this (Patel and Kalhan 1992). Plasma amino acid concentrations are less affected than in organic hyperinsulinism secondary to congenital pancreatic disorders. The characteristic low blood levels of branched-chain amino acids are a not invariable finding (Vejtorp et al. 1977; Soltész et al. 1978), possibly because of other transient disturbances in postnatal metabolic adaptation, including the effects of concurrent asphyxia or hypoxia.

Management must be with the aim of balancing the risks of prolonged and severe hypoglycaemia against the effects of over-intrusive practices, such as unnecessary separation of mother and baby or formula supplementation (Confidential Enquiry into Maternal and Child Health 2007b; National Institute for Health and Clinical Excellence 2008; Hawdon 2010).

Those caring for the baby must regularly monitor the baby for abnormal feeding behaviour and neurological signs, and must document their findings. If at any stage there are abnormal clinical signs, the blood glucose level must be measured and an urgent paediatric review arranged. It is UK national guidance that IDMs should have regular blood glucose monitoring (National Institute for Health and Clinical Excellence 2008). Blood glucose screening may be discontinued when at least two consecutive prefeed blood glucose levels are satisfactory and the baby remains well (see Ch. 34.1).

In the healthy baby, blood glucose monitoring should not commence before 3–4 hours of age in order to avoid 'false positives' associated with the physiological fall in blood glucose. Measurements should be prefeed. It should be noted that test strip reagents are inaccurate, especially at high packed cell volume (Dacombe et al. 1981). Measurement using an accurate method only occurred in 25% of cases in the UK cohort (Confidential Enquiry into Maternal and Child Health 2005).

Hypoglycaemia is usually prevented by supporting early (within 1–2 hours after birth) and frequent breastfeeding, as it has been shown that a feed of 10 ml/kg human milk can cause an increase of blood glucose of the order of 1 mmol/l at this time (Aynsley-Green and Soltész 1985). Additional breast milk or formula supplementation should only occur when indicated by clinical signs and low blood glucose levels. There is evidence in other groups of babies that excessive formula supplementation may impair counterregulatory responses so volumes of formula should be kept to the minimum required (de Rooy and Hawdon 2002).

Sick infants unable to tolerate enteral feeding, or those who remain hypoglycaemic despite full enteral feeds, should receive an intravenous infusion of glucose at an initial rate of 5 mg/kg/min (3 ml/kg/h of 10% dextrose) but increasing rapidly if indicated by repeat blood glucose monitoring. Glucose should not be administered at a rate higher than that required to maintain normoglycaemia, in order to avoid continued stimulation of insulin secretion. Rarely, babies with severe and persistent hyperinsulinism require glucose infusions in excess of 10 mg/kg/min. If enteral feeds have been tolerated these should not be reduced when intravenous glucose is commenced. Neurological signs of hypoglycaemia in any infant warrant immediate correction by a bolus injection of 200–400 mg/kg glucose followed by glucose infusion or increased rate of glucose infusion, the rate being adjusted as necessary to maintain normoglycaemia. In other circumstances, boluses should be avoided as increased insulin secretion and rebound hypoglycaemia will result.

A single injection of glucagon (0.03–0.1 mg/kg), which has a temporary hyperglycaemic effect by releasing glucose from glycogen stores, is a useful measure in the event of delay in siting intravenous lines.

Intravenous glucose should be weaned gradually as indicated by blood glucose monitoring. Rebound hypoglycaemia may occur if the glucose infusion is decreased too quickly.

Iatrogenic complications

Preterm delivery or delivery by caesarean section when there is no clear clinical indication places the baby at risk of unnecessary harm (Hawdon 2010). In addition, frequent failings in postnatal care have been reported to have an impact on the baby's course (Confidential Enquiry into Maternal and Child Health 2005, 2007a, b). These included 'routine' admission of babies to neonatal units, 'routine' supplementation or replacement of breastfeeds with formula, delayed 'skin-to-skin' contact and first feed, poor management of temperature control and testing of blood glucose too soon after birth.

Outcome

According to some studies, infants born after pregnancy complicated by diabetes are at greater risk of brain injury, psychomotor delay, subtle neurological abnormalities and electroencephalogram changes. There are a number of risk factors – placental dysfunction, hypoxia-ischaemia, episodes of maternal ketosis or hypoglycaemia during pregnancy and neonatal hypoglycaemia (Haworth et al. 1976; Rizzo et al. 1995; Stenninger et al. 1998). As these are all interdependent variables it is impossible to determine which is the most important factor. For example, both neonatal hypoglycaemia and adverse neurodevelopmental outcome may be comorbidities following aberrant antenatal metabolic control (Stenninger et al. 1997; Silverman et al. 1998; Ornoy et al. 2001). Studies of well-controlled diabetes in pregnancy show a favourable neurodevelopmental outcome (Persson and Gentz 1984; Rizzo et al. 1994; Sells et al. 1994).

Although many studies have shown that on follow-up the majority of children of mothers with diabetes have normal weight for height and normal height for age, in some cases poor antenatal diabetic control and the presence of neonatal macrosomia (and possibly overfeeding in infancy) increase the risk of obesity in later life (Cummins and Norrish 1980; Vohr et al. 1980; Anonymous 1990; Silverman et al. 1998).

The risk of insulin-dependent diabetes developing by the age of 20 years in the offspring of women with diabetes is at least seven times that for non-diabetic parents, and later impaired glucose tolerance is associated with aberrant diabetic control during pregnancy (Persson and Gentz 1984; Silverman et al. 1998). Interestingly, this is only one-third of the risk reported for the offspring of fathers with insulin-dependent diabetes (Warram et al. 1984) and this is possibly because of a lower rate of DR4 allele transmission from mothers or an effect of programming by the intrauterine environment (Field 1988).

Avoiding harm

Careful medical and obstetric care to achieve strict glycaemic control throughout pregnancy, in combination with appropriate neonatal care, greatly reduces the risk of the many complications discussed

in this chapter. The vast majority of infants of mothers who achieved good diabetic control are of normal size and postnatal metabolic adaptation is normal (King et al. 1982). Therefore it is important to avoid iatrogenic problems such as needless separation of mothers and babies, or practices which impede successful breastfeeding. All hospitals must have written protocols for the prevention and management of potential neonatal complications, including

hypoglycaemia, and for admission to the neonatal unit (National Institute for Health and Clinical Excellence 2008). Unless there are risk factors for other complications (e.g. infection) and as long as the baby appears well, it is not necessary to monitor vital signs (temperature, pulse, respiration rate) or to screen for other potential complications, e.g. polycythaemia (National Institute for Health and Clinical Excellence 2008).

CHAPTER CONTENTS

Epidemiology	395
Perinatal mortality	396
Zygosity	396
Chorionicity	396
Monoamniotic twins	396
Conjoined twins	397
Monochorionic, diamniotic twins	397
Postnatal determination of zygosity	397
Fetal growth in multiple pregnancy	397
Antenatal management	398
Chromosomal anomalies	398
Congenital anomalies	399
Anomalies unique to multiple conception	399
Twin reversed arterial perfusion	399
Death of one fetus	400
Intrapartum management	400
Postnatal management: routine	400
Co-bedding	400
Postnatal management: high-risk care	400
Bereavement	400
Social	401

Epidemiology

Estimates of the incidence of twin conceptions are hampered by the unknown number of abortions and early fetal deaths that occur in multiple pregnancies. Ultrasound studies in early pregnancy sometimes reveal the death and later reabsorption of one fetus in the first

trimester – the vanishing twin syndrome (Landy et al. 1986; Pharoah et al. 2001). Thus, the prevalence of twins at a certain time is all that can be accurately estimated. Furthermore, some multiple births may not be recorded if a pair, one stillborn and one liveborn, are delivered before 24 weeks' gestation. The stillborn would be registered as an abortion and the liveborn baby appears in the records as a single birth.

The incidence of multiple births has steadily increased in the developing countries since the early 1980s (Imaizumi 1997; Kiely and Kiely 2001). In England and Wales it rose from 9.0/1000 births in 1980 to 14.8/1000 in 2001. The incidence has been stable since then, although it has markedly increased among women aged 45 and above (Fig. 23.1). The incidence of triplets rose much faster still until 1998, quadrupling in 15 years. It subsequently declined and in 2008 the rate in England and Wales was 2.4 per 10000 maternities (Office for National Statistics, Birth Statistics 2008).

The increase in multiple births is partly due to assisted reproductive technology (ART), such as ovulation induction and multiple embryo transfer in vitro fertilisation (IVF), in the treatment of sub-fertility (Loos et al. 1998). However, there is also a contribution from the rise in average maternal age (Kiely and Kiely 2001), which is strongly associated with twinning (Fig. 23.1). The rate of twinning associated with ART depends on many aspects of practice, including ultrasonic monitoring of the response to ovulation induction, the number of embryos transferred and the use of selective reduction. There is significant international variation in practice which is mirrored by variation in multiple rates associated with ART, and rates of multiple births are higher in the USA (Kappor and Pal 2009).

Most of the international and temporal variation in twinning is explained by variation in dizygotic (DZ) twinning (see below). This is partly explained by varying use of ART methods, but is also explained by racial variation in the frequency of DZ twinning. In general, black Africans have the highest rates; the Far Eastern, mongolian, races the lowest; the rates for Asian Indians and Caucasians lie between these. The prevalence of monozygotic (MZ) twin births had been constant worldwide at 3.5/1000 maternities until recently. A small increase in the MZ twinning rate has been noted since the 1980s (Allen and Parisi 1990) and this may also reflect increased use of ART as separation of an embryo into MZ twins is more common with IVF conceptions.

Perinatal mortality

The perinatal mortality rate is over four times higher in twins and four to nine times higher in triplets. The increased rate of loss in multiples is explained by an increased risk of both stillbirth and neonatal death. In an annual review of all births and perinatal deaths in Scotland in 2007, the risk of stillbirth in multiple births was 16.1 per 1000, compared with the risk in singletons of 5.3 per 1000 (Information Services Division, NHS Scotland 2008). The risk of neonatal death in multiples was 18.0 per 1000, compared with the risk in singletons of 2.8 per 1000. The majority of the stillbirths lacked a clear explanation for the death, whereas the majority of the neonatal deaths were related to prematurity. The risk of stillbirth is strongly associated with chorionicity and this is discussed below. There is also an increased risk of death of the second twin as a result of anoxia, arising from complications following vaginal birth of the second twin, which is apparent in term births following vaginal delivery of twin one but is not apparent among infants delivered by elective caesarean section (Smith et al. 2005). Twins conceived as a result of infertility treatment tend to be delivered earlier and to be of lower birthweight than spontaneously conceived twins (Lambalk and van Hooff 2001), and babies from these pregnancies have a higher perinatal mortality rate than those spontaneously conceived (Hurst and Lancaster 2001). The explanation is uncertain but the cause of the parental subfertility may be a contributory factor.

Fig. 23.1 Trends between 1998 and 2008 in twin births (per 10 000 maternities), with illustration of rates within some age categories. (Data from Office for National Statistics, *Birth Statistics* (2008).)

Zygosity

DZ twins arise when two ova are released and fertilised in one menstrual cycle, whereas MZ twins arise when one ovum is fertilised and the resulting zygote divides into two. The ratio of MZ to DZ twins varies in different populations. In the UK approximately two-thirds are DZ, so, in all, about one-third of the pairs will be of unlike sex, one-third both girls and one-third both boys. MZ splitting appears to be 6–12 times more common following ovulation stimulation, whether or not fertilisation took place in vitro (Derom et al. 2000; Blickstein et al. 2003). There also appear to be some extremely rare examples of MZ twinning occurring as an autosomal-dominant trait (Segreti et al. 1979). DZ twinning is known to be affected by a number of factors in addition to race, many of which appear to be related to differing maternal gonadotrophin levels. The rates are known to increase with maternal age, height, parity and frequency of intercourse (MacGillivray et al. 1988).

Chorionicity

Given that there are two fetal membranes, the amnion and chorion, there are three possible combinations of sacs in twin pregnancy:

1. both twins may have completely independent membranes: dichorionic and diamniotic (DCDA)
2. both twins may have separate amnions but share the chorion: monochorionic, diamniotic (MCDA)
3. both twins may share both membranes: monoamniotic (MA).

The relationship between chorionicity and zygosity is complex (Fig. 23.2). For practical purposes, MCDA and MA twins are invariably MZ. However, DCDA can follow both MZ and DZ twinning and further tests are required postnatally to determine zygosity in non-sex-discordant twins. Chorionicity is best determined by ultrasound in the first trimester of pregnancy (see Ch. 9 and Fig. 9.14) when the presence of the lambda sign (DCDA) or T sign (MCDA) has an accuracy close to 100% (Shetty and Smith 2005). However, even in the third trimester, chorionicity can be determined with reasonable accuracy. Diagnosis of MA twinning requires detailed and expert assessment as a thin dividing membrane can easily be missed with suboptimal ultrasound.

Monoamniotic twins

MA twins arise when the splitting of the single zygote is delayed until the end of the second week after fertilisation and account for approximately 1% of MZ twin pregnancies. Earlier studies have

Fig. 23.2 Relationship between zygosity and chorionicity. (Reproduced with permission from Multiple Births Foundation (1997).)
